

Does IT help?

Information Technology in Banking and Entrepreneurship

May 2022

Abstract

This paper provides novel evidence on the importance of information technology (IT) in banking for entrepreneurship. To guide our analysis, we build a parsimonious model of bank screening and lending. The model predicts that IT in banking can spur entrepreneurship by making it easier for startups to borrow against collateral. We empirically show that job creation by young firms is stronger in US counties that are more exposed to IT-intensive banks. Consistent with a strengthened collateral channel, entrepreneurship increases by more in IT-exposed counties when house prices rise. Regressions at the bank level further show that banks' IT adoption makes credit supply more responsive to changes in local house prices, and reduces the importance of geographical distance between borrowers and lenders. These results suggest that IT adoption in the financial sector can increase dynamism by improving startups' access to finance.

JEL classification: D82, G21, L26.

Keywords: technology in banking, entrepreneurship, information technology, collateral, screening.

1 Introduction

The rise of information technology (IT) in the financial sector has dramatically changed how information is gathered, processed, and analyzed (Liberti and Petersen, 2019; Vives, 2019). This development has important implications for credit supply, as one of banks' key functions is to screen and monitor borrowers. Financing for young firms is likely to be especially sensitive to such changes in lenders' technology. They have produced limited information available to lenders and often rely on banks as a source of funding (Robb and Robinson, 2014; Babina, 2020).¹ And yet, despite startups' disproportionate contribution to job creation, innovation, and growth (Klenow and Li, 2020), evidence on how the IT revolution in banking affects their access to finance and job creation remains scarce.

This paper analyzes theoretically and empirically how the rise of IT in the financial sector affects entrepreneurship. We first build a parsimonious model of bank screening and lending. Banks face 'old' and 'young' firms of heterogeneous unobserved quality. They can screen firms by either acquiring information about firms' projects or by requiring collateral. Crucially, IT makes it relatively cheaper for banks to process and transmit the value of collateral, and thus engage in collateralized lending.² IT thereby benefits young firms, as they have not yet produced sufficient information (i.e. they are opaque) and have to provide collateral to obtain a loan. A key prediction of the model is thus that IT in banking spurs entrepreneurship, and the more so when the value of collateral rises.

We provide evidence at the county and bank level consistent with the model's predictions. We use detailed data on the purchase of IT equipment of commercial banks across the United States in the years before the Great Financial Crisis (GFC).³ First, at the county level, we find that counties where IT-intensive banks operate experience

¹According to Robb and Robinson (2014) and Kerr and Nanda (2015), banks play an outsized role in financing startups, often through owner-backed loans.

²IT facilitates real estate appraisal and firms' ability to access and transmit the associated information (Kummerow and Lun, 2005; Sawyer et al., 2005), as well as the flow of information within banks (Petersen and Rajan, 2002). We thus assume that screening through collateral is relatively cheaper for IT-intensive banks.

³The absence of major financial regulatory changes during our sample period from 1999-2007 makes it well-suited to identify the effects of IT in banking on entrepreneurship. The period after the GFC is characterized by substantial financial regulatory reform (such as the Dodd-Frank Act and regular stress tests) and encompassing government programs, both of which have affected banks' lending decisions, especially to small firms. A further reason to exclude the GFC and the following years from the analysis is that during the crisis IT adoption determined the performance of mortgages originated by banks (Pierri and Timmer, 2022), thus creating a potential confounding factor.

stronger job creation by startups. Moreover, the presence of IT-intensive banks strengthens the responsiveness of job creation by entrepreneurs to changes in local real estate values. This pattern is especially pronounced in industries that rely more on real estate collateral. Second, in bank-county level regressions we show that small business lending of IT-intensive banks is more responsive to changes in local house prices and that IT attenuates the importance of lender-borrower distance, and hence informational frictions, in lending to small firms. Instrumental variable (IV) regressions confirm these findings.

To measure banks' IT adoption, we follow seminal papers on IT adoption among non-financial firms (Bresnahan et al., 2002; Brynjolfsson and Hitt, 2003; Beaudry et al., 2010; Bloom et al., 2012). We measure IT adoption at the bank-branch level as the ratio of PCs per employee within each bank. This simple measure of IT adoption, which is based only on hardware availability, is a strong predictor of alternative measures, such as the IT budget or adoption of frontier technologies, but has much better data coverage.⁴ We purposely focus on banks' general adoption of IT, rather than specific technologies (e.g. ATMs or online banking as in Hannan and McDowell (1987) or Hernández-Murillo et al. (2010)), because of the multi-purpose nature of IT. As argued by Petersen and Rajan (2002), information technology has transformed the financial sector along many inter-linked dimensions, rather than just in narrow segments. Consistently, our analyses aim to shed light on the economic mechanisms behind the effects of IT adoption, rather than on the impact of specific IT applications.

Following Pierri and Timmer (2022), we decompose IT adoption into a bank fixed effect, which constitutes our main measure of IT at the bank level, and a borrower-county fixed effect. This additive model allows us to purge bank-level IT adoption from unobservable local factors that could affect the IT intensity of local branches; a large literature has adopted similar approaches to disentangle supply and demand forces (Khwaja and Mian, 2008; Amiti and Weinstein, 2018).

We use banks' IT adoption and their historical geographic footprint to compute county-level *exposure* to IT in the banking sector. Specifically, county exposure is computed as the weighted average bank-level IT adoption of banks operating in a given county, with weights given by the initial share of local branches. Constructing local

⁴Later waves of the CiTBDs Aberdeen data on IT usage provide additional information on the IT-budget and adoption of cloud computing at the establishment level. The number of PCs per employee is a strong predictor of these measures of IT adoption in 2016. For example, the bank-level correlation between the per capita share of PCs and the IT budget is 65%. The measure has also been shown to be a valid proxy in the non-financial sector, for instance to predict firm productivity or local wage growth (Bresnahan et al., 2002; Beaudry et al., 2010; Bloom et al., 2012).

IT exposure from banks' historical footprint ameliorates concerns about banks' selecting into counties based on unobservable county characteristics, such as economic dynamism or growth trajectories. Consequently, we find that county exposure is not systematically correlated with several county-level characteristics, such as the unemployment rate, level of education, industry composition, or the use of IT in the *non-financial* sector.

The first part of the empirical analysis shows that higher county-level IT exposure is associated with significantly higher entrepreneurial activity. Entrepreneurship is measured as the employment share of firms of age 0 to 1, as in [Adelino et al. \(2017\)](#). Economically, our estimates imply that a one-standard-deviation higher IT exposure is associated with a 0.4 percentage points (pp) higher employment share in young firms. In light of the steady decline in the employment share of young firms – which fell by around 3 pp since the 1990s – the economic magnitude is sizeable. Our findings thus suggest that banks' IT adoption partly offset the decline in firm formation.

In principle, the positive relation between IT exposure and startup activity could be explained by reverse causality or omitted variable bias. Reverse causality is unlikely to be a major concern in our empirical setting: lending to startups represents only a small fraction of banks' overall lending, which makes it unlikely that banks' overall IT adoption is driven solely by an expected increase in startup activity in specific counties. Yet confounding factors could drive the association between IT and entrepreneurship. For instance, a better-educated workforce may make it easier for banks to hire IT-savvy staff and also create more business opportunities for startups.

To mitigate these concerns, we show that including a wide set of county-level controls, including the IT adoption of non-financial firms, does not affect the results, and neither does excluding counties in which venture capital financing plays an outsized role. Similarly, we find results similar to regressions in levels when we estimate a regression in changes, which differences out any potential observed and unobserved time-invariant county-specific characteristics that could bias our results. We examine the robustness of the link between IT exposure and startup activity with several additional analyses. Exploiting county-industry variation, we find that job creation by startups in counties more exposed to IT is relatively larger in industries that depend more on external financing ([Rajan and Zingales, 1998](#)). This pattern remains similar in regressions without and with industry and county fixed effects, even though the R-squared increases significantly. This suggests that the relationship between entrepreneurship and IT is likely driven by better access to finance, and not other unobservable county or industry factors ([Altonji et al.](#),

2005; Oster, 2019).

Another possible concern with our empirical analysis is that banks' IT could capture other bank-specific factors, such as differences in business models or quality and profitability. Therefore, we compute counties' exposure to several bank characteristics, eg size, funding or assets structure, capitalization, and profitability. We find that the relationship between entrepreneurship and local IT is unchanged when such controls are included, mitigating the concern that IT is spuriously capturing other bank factors. In addition, we use instrumental variable regressions at the bank-county-level. As discussed in detail below, this complementary analysis also allows us to control for unobservable factors at the local- or bank-level through granular fixed effects.

Guided by the model, we then investigate the channels underlying the relationship between county exposure and entrepreneurship. The model assumes a comparative advantage of high-IT banks to lend against collateral. This assumption is based on two reinforcing trends. First, advances in technology reduce the costs of several real estate-related processes, for example by expediting appraisal, research, and sales, as well as accessing and transmitting such information across distances and institutions (Jud et al., 2002; Kummerow and Lun, 2005; Sawyer et al., 2005).⁵ Second, IT facilitates the flow of information, such as on collateral values, between banks' headquarters and local branches (Petersen and Rajan, 2002).⁶

We investigate whether IT exposure affects the relation between higher collateral values and startup activity by exploiting variation in house price growth across counties (Mian and Sufi, 2011). We thereby follow literature showing that entrepreneurs often pledge their home equity as collateral (Adelino et al., 2015; Bahaj et al., 2020). Consistent with the model's predictions, we find that job creation by startups increases by more when collateral values rise, and especially so in IT-exposed counties. The amplifying effect of IT exposure is strongest in industries where home equity is of high importance for startups – measured either by firms' propensity to use home equity or the amount of startup capital required to start a business (Hurst and Lusardi, 2004; Adelino et al., 2015; Doerr, 2021).

⁵For example, Kummerow and Lun (2005) argue that “firms [used to] access sales data on microfiche, a tedious, time-consuming search process. [...] The result of being able to obtain sales information more quickly by fax or email was to increase the number of valuations completed per day. [...] A process that used to take several days could be compressed to a few hours. Valuers who used to do 3–4 valuations a day, now can complete 7–8 per day, including property inspections”.

⁶Consistent with a cost advantage of high IT banks for collateralized lending, in an accessory analysis we use loan-level data on corporate lending to show that banks with a higher degree of IT adoption are more likely to request collateral for their lending, even when controlling for unobservable borrower characteristics.

Exploiting county-industry variation allows us to control for observed and unobserved heterogeneity at the county and industry level through granular fixed effects. Including these fixed effects has no material effect on our estimated coefficients, despite increasing the R^2 substantially. This pattern mitigates the concern that unobservable factors explain the correlation between IT in banking, house prices, and entrepreneurship (Altonji et al., 2005; Oster, 2019).

Two further predictions of the model concern recourse and startup quality. First, the ability to recourse borrowers' assets or income in the case of default can partially substitute for the need of screening borrowers through collateral (Ghent and Kudlyak, 2011). Exploiting differences in laws on recourse loans across states, we find that in recourse states the positive relationship between IT exposure and entrepreneurship is weaker. These findings are consistent with the central role of collateral underlying the relation between IT in banking and entrepreneurship in the model. Second, the model predicts that higher startup activity does not result in lower average quality, as it results from a better screening technology through IT. While it is difficult to accurately measure startups' quality, we find no relation between IT exposure and job creation among young continuing firms (i.e. in the transition rates from firms of age 0–1 to age 2–3, or from 2–3 to 4–5). This pattern indicates that stronger firm formation does not result in more exits, which would indicate that firms of lower quality were started. IT in banking could thus spur aggregate business dynamism.

The second part of the empirical analysis uses granular bank-county level data on small business lending to shed light on the effects of IT adoption on bank lending. This analysis allows us to measure IT at the bank-level directly, which brings two main advantages. First, we can use an instrumental variable to obtain exogenous variation in banks' IT adoption. And second, it allows us to additionally include granular fixed effects that control for potentially confounding factors that could affect loan demand.

We develop an instrumental variable to address the concern that banks' IT adoption could be correlated with other (unobservable) bank characteristics that also drive lending to small businesses. Our instrument is based on the distance between a bank's headquarters (HQ) and the nearest land-grant colleges, in the spirit of He et al. (2021) and Pierri and Timmer (2022). Students of these colleges, established at the end of the nineteenth century to provide technical education, are significantly more likely to major in technical subjects than other students. The establishment of these colleges thus fosters the local presence of technical knowledge and expertise. Importantly, the location of land-grant

colleges within a state is partly due to historical accidents and it is practically random from today's perspective (Moretti, 2004). Moreover, the location of banks' HQ is mostly explained by historical heritage, it usually predates the IT revolution by decades, and it is uncorrelated with the presence of land-grant colleges in a county. Consistent with the hypothesis that availability of technical knowledge fosters IT adoption, we find a strong negative correlation between banks' IT adoption and the distance between banks' HQ and land-grant colleges. We focus on HQ locations because HQ-based workers are likely to have an outsized influence on their company as they have a higher position or are in closer contact with top executives (the important contribution of headquarters to a company's performance is well-documented (Giroud, 2013, e.g.)).

The distance from land-grant colleges, by fostering technical knowledge, could also affect local economic conditions, businesses, and entrepreneurship. However, our empirical setting allows us to address this concern directly: as we include county*year fixed effects, we effectively compare lending to borrowers in the same county by different banks (with headquarters that have different distances to land-grant colleges). Our instrumental variable estimates are therefore unaffected by potentially confounding factors that may determine local credit demand, including human capital, technology adoption, and the distance from land-grant colleges.

We revisit the models' predictions on the interaction of IT, house prices, and firms' access to credit. We find that small business lending by high-IT banks is more sensitive to changes in local house prices. This evidence suggests that high-IT banks lend more when real estate collateral values increase, in line with the model's predictions and our findings on job creation at the county-level. This finding is robust to specifications in which we account for unobservable time-varying factors at the county level through county*year fixed effects. This mitigates concerns that the relation between bank lending and house prices is due to (unobservable) confounding factors, such as employment growth. In addition, our IV results confirm that IT-savvy banks lend more to small businesses when house prices rise, even when holding unobservable county factors (such as loan demand) constant.

The model predicts that greater physical distance can increase informational frictions between borrowers and lenders, thereby increasing the importance of hard information that can be easily transmitted from local branches to (distant) headquarters (see also Petersen and Rajan (2002); Liberti and Petersen (2019); Vives and Ye (2020)). We hence study how physical distance affects bank lending in response to a local increase

in business opportunities (i.e. a change in the demand for credit), measured by local growth in income per capita (Adelino et al., 2017). We show that, first, the sensitivity of banks' small business lending to a local income shock declines in the distance of the county to banks' HQ, even when we include county*time fixed effects. This is in line with the interpretation that a greater distance implies higher frictions. Consistent with the model, however, the effect of distance on the sensitivity of lending to a rise in business opportunities is significantly lower for IT-intensive banks.⁷ Again, IV regressions yield similar results in terms of economic and statistical significance.

In a final step we note that, as IT in banking spurs entrepreneurship through a collateral channel, a potential side effect is that it may also magnify underlying wealth gaps. Banks' IT may strengthen the connection between personal/family wealth and entrepreneurship rather than expanding entrepreneurship opportunities for groups, racial minorities in particular, that face more difficult access to capital, long-lasting discrimination on mortgage markets, or slower wealth accumulation. Consistently, we find suggestive evidence that IT has a negative association with the share of black entrepreneurs in a county, so its positive overall impact on local economic dynamism may come at the expense of higher inequality.

It is important to note that our findings do not preclude that banks' IT adoption affects startups through additional channels. For example, IT could also affect how hard information beyond the quality and value of real estate collateral is transmitted and processed Petersen and Rajan (2002). For example, in the context of IT-intensive fintech lenders, Di Maggio and Yao (2021) show that hard information embodied in credit reports explains most of the variation in interest rates. That being said, as borrowing against real estate collateral constitutes an important source of financing for entrepreneurs, our results suggest that banks' IT adoption has improved entrepreneurs' access to bank loans.

Literature and contribution. Our paper contributes to the literature on financial technology and banking. Banks' increasing technological sophistication could enable them to more efficiently screen and monitor new clients (Hauswald and Marquez, 2003), increase the importance of hard information (Petersen and Rajan, 2002; Liberti and Mian, 2009), and consequently be more resilient to shocks (Pierri and Timmer, 2022). Another implication is that IT adoption by banks leads to greater lender-borrower distance (Petersen,

⁷Our findings are also in line with literature documenting a trend toward greater average distances between banks and their borrowers (Granja et al., forthcoming).

1999; Berger and Udell, 2002; Hauswald and Marquez, 2006) and an expansion in branch networks (Lin et al., 2021). These papers also imply that IT affects the supply of credit, but empirical evidence is scarce. An exception are D’Andrea and Limodio (2019), who show how high-speed internet promoted credit provision by African banks, likely through their adoption of new financial technologies and improved liquidity management. We provide novel evidence that banks’ IT adoption can spur bank lending against collateral and in distant counties, and thereby increase employment among startups.

We also relate to papers that highlight the importance of housing collateral for corporate investment (Catherine et al., forthcoming; Chaney et al., 2012) and entrepreneurial activity (Hurst and Lusardi, 2004; Adelino et al., 2015; Corradin and Popov, 2015; Schmalz et al., 2017; Bahaj et al., 2020). Problems of asymmetric information about the quality of new borrowers are especially acute for young firms that are costly to screen and monitor (Degryse and Ongena, 2005; Agarwal and Hauswald, 2010). To overcome the friction, banks often require collateral until they acquired sufficient information (Jiménez et al., 2006; Hollander and Verriest, 2016; Prilmeier, 2017). Our results suggest that the rise of IT in the financial sector has further increased the importance of housing collateral to entrepreneurs.

Finally, we speak to the recent literature that investigates how the rise of financial technology changes information processing and the resulting consequences for households (Berg et al., 2019; Fuster et al., 2021) and firms (Hau et al., 2018; Erel and Liebersohn, 2020; Beaumont et al., 2021; Gopal and Schnabl, 2021; Kwan et al., 2021). Importantly, Fuster et al. (2019) and Di Maggio and Yao (2021) argue that FinTechs rely disproportionately on hard information in the process of granting loans. Our results suggest that the same is true for banks with higher IT adoption. In addition, we document material effects for firms’ access to credit and employment, reflecting the importance of bank lending to young and small firms (Robb and Robinson, 2014). An advantage of focusing on variation in IT adoption among banks is that our results are unlikely to be explained by regulatory arbitrage, which has been shown to be a driver of the growth of FinTechs (Buchak et al., 2018).

The remainder of the paper is structured as follows. Section 2 presents a simple model of bank screening and lending. Section 3 provides an overview of our data. Section 4 presents empirical tests for the main predictions of the model at the county level and Section 5 at the bank-county level. Section 6 provides additional evidence supporting the model assumptions, as well as robustness tests. Section 7 concludes.

2 A Model of Bank Screening and Lending

We develop a parsimonious model to assess the implications of banks' IT adoption for screening and lending. A key building block is asymmetric information: firms' quality is initially unobserved by banks. To mitigate the arising adverse selection problem, banks screen by either acquiring information about firms to learn their type (unsecured lending) or requesting collateral (secured lending). We describe the effects of banks' IT adoption on lending to young firms and derive six predictions tested in the subsequent empirical analysis.

The agents in the economy are banks and firms. There are two dates $t = 0, 1$, no discounting, and universal risk-neutrality. There are two goods: a good for consumption or investment and collateral that can back borrowing at date 0.

Firms have a new project at date 0 that requires one unit of investment. They are penniless in terms of the investment good but have pledgeable collateral C at date 0. Firms are heterogeneous at date 0 along two publicly observable dimensions. First, a firm's collateral is drawn from a continuous distribution G . The market price of collateral at date 1 (in terms of consumption goods) is P , so the collateral value is PC . Second, firms are either old (O) or young (Y), where we refer to young firms as entrepreneurs. The mass of firms is normalized to one and the share of young firms is $y \in (0, 1)$. For expositional clarity, firm age and collateral are independent.

The key friction is asymmetric information about a firm's type, that is the quality of the project. The project yields a contractible payoff $x > 1$ at date 1 if successful and 0 if unsuccessful. Projects of good firms are more likely to be successful: the probability of success is p_G for good firms and p_B for bad ones, where $0 < p_B < p_G < 1$ and only good projects have a positive NPV,

$$p_B x < 1 < p_G x. \tag{1}$$

Project quality (type G or B) is privately observed by the firm but not by banks. The share of good projects at date 0 is $q > 0$, which is independent of bank or firm characteristics. We assume that the share of good projects is low,

$$[qp_G + (1 - q)p_B] x < 1, \tag{2}$$

so the adverse selection problem is severe enough for banks to choose to screen all borrowers in equilibrium. As a result, all loans granted are made to good firms.

There is a unit mass of banks endowed with one unit of the investment good at date 0 to grant a loan. An exogenous fraction $h \in (0, 1)$ of banks adopted IT in the past and is therefore a high-IT bank, while the remainder is a low-IT bank.

Each bank has two tools to screen borrowers. First, the bank can pay a fixed cost F to learn the type of the project (screening by information acquisition). This cost can be interpreted as the time cost of a loan officer identifying the quality of the project. We assume that this cost is lower for old firms than for young firms:

$$F_O < F_Y, \tag{3}$$

which captures that old firms have (i) a longer track record and thus lower uncertainty about future prospects; or (ii) larger median loan volumes in practice, so the fixed cost is relatively less important.

Second, the bank can screen by asking for collateral at date 0 that is repossessed and sold at date 1 if the firm defaults on the loan. In this case, the bank does not directly learn the firm’s type, but the self-selection by firms—whereby only firms with good projects choose to seek funding from banks—reveals their type in equilibrium. We assume that the cost of screening via collateral is lower for high-IT banks than for low-IT banks:

$$v_{HighIT} < v_{LowIT}, \tag{4}$$

which captures that it is easier or cheaper for a high-IT bank to verify the existence of collateral, determine its market value, or document and convey these pieces of information to its headquarters. This assumption builds on literature that has shown that IT has facilitated the appraisal of real estate as well as accessing and transmitting such information across distances and institutions ([Jud et al., 2002](#); [Kummerow and Lun, 2005](#); [Sawyer et al., 2005](#)).⁸

⁸[Kummerow and Lun \(2005\)](#) argue that “appraisal firms [used to] access sales data on microfiche, a tedious, time-consuming search process. [...] being able to obtain sales information [electronically] more quickly [means that] process that used to take several days could be compressed to a few hours. Valuers who used to do 3–4 valuations a day, now can complete 7–8 per day, including property inspections.” [Sawyer et al. \(2005\)](#) highlight that “the use of digital forms [...] and online applications [...] provide[s] semi-automation [and] leads to an increasing percentage of the transaction information being shared in digital form, discussions about standardizing the form and structure of data, and the use of this data for analysis and additional value-adding functions.” More recent industry reports suggest that the process continues today: “Leveraging big data streamlines the appraisal process, reducing to seconds complex analyses that used to take hours” (see [How Technology is Shaping the Appraisal Process and Profession](#)). Further, [Table A1](#) provides evidence consistent with this assumption, showing that high-IT banks issue

For expositional clarity the fixed costs F are independent of the bank's type and the costs of screening via collateral v are independent of firm age. Our results generalize as long as the high-IT bank has a comparative advantage in screening via collateral.

We assume that banks and firms are randomly matched. The lending volume maximizes joint surplus, where banks receive a fraction $\theta \in (0, 1)$ of the surplus generated. This assumption simplifies the market structure because it implies that a startup does not make loan application with multiple banks, thus excluding competitive interaction between lenders. Our approach is supported by evidence that the degree of local concentration does not affect the relationship between IT and entrepreneurship (see [Table A2](#)).

In what follows, we assume a ranking of screening costs relative to the expected surplus of good projects:

$$v_{HighIT} < F_O < p_G x - 1 < \min\{F_Y, v_{LowIT}\}. \quad (5)$$

In equilibrium, only good firms may receive credit because all firms are screened in some way to detect lemons. Young firms with a good project cannot receive credit from a low-IT bank because the information cost is too high, as implied by the assumption in (5). (For a relaxation of this assumption, see [Extension 2](#) below.) Young firms with a good project receive credit when matched with a high-IT bank and when possessing enough collateral, $C > C_{min}$, which applies to a fraction $1 - G(C_{min})$ of these firms. The bound on the collateral C_{min} ensures that young firms of the bad type do not pretend to be of good type, so the binding incentive compatibility constraint is

$$p_B(x - r) \equiv (1 - p_B)PC_{min}, \quad (6)$$

where r is the bank's lending rate.⁹ Equation 6 has an intuitive interpretation: its left-hand side is the benefit of pretending to be a good type and receiving a loan from a bank, keeping the surplus $x - r$ whenever the project succeeds, which happens with the success probability of the bad type p_B . The right-hand side is the cost of forgoing the market value of collateral when the project fails. Equation (6) makes clear that the minimum level of collateral depends negatively on its price, $C_{min} = C_{min}(P)$ with $\frac{dC_{min}}{dP} < 0$. In sum, sufficient collateral ensures that only good firms receive loans in equilibrium.

Old firms with a good project always receive credit. When matched to a high-IT bank,

more secured loans in the syndicated loans market.

⁹When the bank has adopted IT, its cost of lending is $1 + v_{HighIT}$ and the surplus from lending is $p_G x - (1 + v_{HighIT})$ in equilibrium because only firms with a good project are funded. Since the bank keeps a fraction θ of this surplus, the equilibrium lending rate is $r_{HighIT}^* = \theta p_G x + (1 - \theta)(1 + v_{HighIT})$.

lending is backed by collateral if the firm has enough of it, otherwise the high-IT bank ensures the project quality via information acquisition. When matched with a low-IT bank, screening via information acquisition is exclusively used (see also Extension 2).

Together, these points allows us to state the model's predictions about the share of expected lending to young firms s_Y (out of total expected lending) and how it depends on the share of high-IT banks h and the collateral price P . See Appendix A1.1 for proofs.

Proposition 1 *The share of lending to young firms is*

$$s_Y \equiv \frac{yh[1 - G(C_{min})]}{1 - y + yh[1 - G(C_{min})]}. \quad (7)$$

The first three predictions describe the comparative statics.

Prediction 1. A higher share of high-IT banks increases the share of lending to young firms, $\frac{ds_Y}{dh} > 0$.

Prediction 2. Higher collateral values increases the share of lending to young firms, $\frac{ds_Y}{dP} > 0$.

Prediction 3. Higher collateral values increase the share of lending to young firms by more when the share of high-IT banks is higher, $\frac{d^2s_Y}{dh dP} > 0$.

To gain intuition for these predictions, note that a higher share of high-IT banks implies that good young firms with sufficient collateral can receive funding more often (because they are matched with a bank that lends to them more often). A higher value of collateral, in turn, lowers the minimum collateral requirement C_{min} and thus increases expected lending along the extensive margin (more young firms have sufficient collateral).

In equilibrium, all potential borrowers are screened and only good projects are financed, regardless of the screening choice or the bank type. Thus, the model implies that IT adoption does not affect the quality of firms who are funded by banks, as summarized in the following prediction.

Prediction 4. Bank IT adoption does not affect the quality (default rate) of firms receiving funding in equilibrium.

Some of our model's implications are related to evidence documented in other work. The positive impact of collateral values on entrepreneurship is consistent with the evidence in [Adelino et al. \(2015\)](#), among others. Moreover, young firms use collateral more extensively than old firms in equilibrium. Since firm age and size are correlated in

the data, this implication is consistent with recent evidence on the greater importance of collateral for lending to small businesses (Gopal, 2019; Chodorow-Reich et al., 2021; Custodio et al., 2021).

Finally, we consider two model extensions to derive additional implications.

Extension 1: Recourse. Recourse – i.e. lenders’ ability to possess other borrower assets or future income through a deficiency judgment – can substitute for the need of screening borrowers through collateral. To study the role of recourse, we assume that a fraction $i \in (0, 1)$ of firms generate an additional external income I at date 1. Banks may have recourse to this income, depending on whether they are located in states with recourse (R) or with no recourse (NR). In recourse states, all banks can obtain this external income, while only high-IT banks have the comparative advantage in lending via collateral. For expositional clarity, we assume that the external income is independent of other firm characteristics and that it suffices to back the loan, $I \geq PC_{min}$.

Nothing changes in no-recourse states, so the share of lending to young firms is $s_Y^{NR} = s_Y$ given in Equation 7. In recourse states, by contrast, young firms now also receive funding when they have additional income (a fraction i of them do). Because their future income is no smaller than the collateral value, no additional incentive problems arise and only young firms of high quality seek funding. Thus, the share of lending to young firms in recourse states is

$$s_Y^R \equiv \frac{y \{i + (1 - i)h[1 - G(C_{min})]\}}{1 - y + y \{i + (1 - i)h[1 - G(C_{min})]\}}. \quad (8)$$

The next prediction compares recourse to no-recourse states.

Prediction 5. A higher share of high-IT banks increases the share of lending to young firms by less in recourse states than in non-recourse states, $\frac{ds_Y^{NR}}{dh} > \frac{ds_Y^R}{dh}$.

Quite intuitively, this result arises because recourse to future income mitigates the effective comparative advantage of high-IT banks in using collateral.

Extension 2: Geographical distance. A large literature in banking highlights the importance of geographical distance between lenders and borrowers and how it affects the relative values of hard and soft information. In our model, high-IT banks have a comparative advantage in screening based on collateral, which can be interpreted as hard-information lending (and is thus unaffected by distance). Low-IT banks lend based

on information acquisition instead. To allow for a role of distance, we assume that low-IT banks can screen some young firms, namely those that are close. Hence, we relax Assumption 5 by assuming

$$v_{HighIT} < F_Y^{close} < p_G x - 1 < \min\{F_Y^{distant}, v_{LowIT}\}, \quad (9)$$

where the cost of information acquisition is low enough relative to the expected surplus of a good project when the firm is close to the bank. Let $d \in (0, 1)$ be the fraction of young firms that is distant and the remainder is close.

Thus we can express for each type of bank the share of credit to young firms as a proportion of total credit, ϕ , and how it depends on the bank's distance to the borrower. For a high-IT bank, this share is invariant to distance:

$$\phi_{HighIT} = \frac{y[1 - G(C_{min})]}{y[1 - G(C_{min})] + 1 - y} = \phi_{HighIT}^{distant} = \phi_{HighIT}^{close}, \quad (10)$$

because all young firms with sufficient collateral are funded (irrespective of distance). For a low-IT bank, by contrast, this share depends on distance:

$$\phi_{LowIT}^{distant} = 0 < \frac{y(1 - d)}{y(1 - d) + 1 - y} = \phi_{LowIT}^{close}, \quad (11)$$

because no distant young firms are funded, but geographically close ones are. Note that when most young firms are distant (a high d), we have $\phi_{HighIT} > \phi_{LowIT}^{close}$. Also note that the shares of low-IT banks are independent of the price of collateral, so $\frac{d\phi_{LowIT}}{dP} = 0$.

Prediction 6. Geographic distance between lenders and borrowers matters more for low-IT banks than that of high-IT banks. Specifically, the share of lending to young firms varies more with distance for low-IT banks than for high-IT banks:

$$\phi_{LowIT}^{close} - \phi_{LowIT}^{distant} > \phi_{HighIT}^{close} - \phi_{HighIT}^{distant}. \quad (12)$$

The advantage of high-IT banks in hard information lending makes their lending less sensitive to the lender-borrower distance. Of particular relevance for the empirical analysis is how the distance between borrowers and lenders impacts the sensitivity of credit to local economic conditions. [Adelino et al. \(2017\)](#) document that startups strongly respond to changes in economic opportunities and are responsible for a larger share of job creation when local opportunities arise thanks to a positive income shock. As the

responsiveness of startup activity to local shocks is larger than for older firms, the more a bank lends to startups in a market, the larger its credit supply should respond to local economic conditions. Therefore, **Prediction 6** implies that low IT banks’ credit responds less to local economic conditions in counties that are more-distant from the banks’ HQ, while distance does not matter for the responsiveness of lending by high IT banks.

3 Data and Variable Construction

This section explains the construction of the main variables and reports summary statistics. The analysis focuses on the years from 1999 to 2007. While banks continued to adopt IT in more recent years, the post-crisis period saw substantial financial regulatory reform (such as the Dodd-Frank Act and regular stress tests), which has affected banks’ ability to lend to young and small firms. The absence of major financial regulatory changes during our sample period makes it well-suited to identify the effects of banks’ IT on entrepreneurship.

IT adoption and exposure. Data on banks’ IT adoption come from an establishment-level survey on personal computers per employee in establishment across the U.S. by CiTBDs Aberdeen (previously known as “Harte Hanks”) for the years 1999, 2003, 2004, and 2006. We focus on establishments in the banking sector (based on the SIC2 classification and excluding savings institutions and credit unions). We end up with 143,607 establishment-year observations .

Our main measure of bank-level IT adoption is based on the use of personal computers across establishments. To construct county-level exposure to bank IT adoption, we proceed as follows. We first hand-merge the CiTBD Aberdeen data with data on bank holding companies (BHCs) collected by the Federal Reserve Bank of Chicago. We use the Financial Institution Reports, which provide consolidated balance sheet information and income statements for domestic BHCs. We then compute a BHC-level measure of IT adoption from a regression of the share of personal computers per employee in each bank branch on a bank (group) fixed effect, while controlling for the size of the establishment and the location of the establishment, as well other characteristics through fixed effects at the level of the establishment county. Specifically, we estimate $PCs/Emp_{est,t} = \widetilde{IT}_{BHC} + \theta_{BHC\ type} + \theta_c + \theta_t + \gamma \cdot \log(emp_{est}) + \epsilon_{est,t}$. The variation captured by the bank fixed effects, denoted as \widetilde{IT}_{BHC} , is our main measure of IT adoption

at the bank level. The focus on BHCs rather than local branches or banks is due to the facts that (a) most of the variation in branch-level IT adoption is explained by variation at the BHC-level, (b) technology adoption at individual branches could in principle be influenced by unobservable county-level factors, which we account for through branch-location fixed effects, and (c) using a larger pool of observations reduces measurement error.

To compute county exposure to IT in the financial sector, we then merge the resulting Aberdeen-BHC data set to the FDIC summary of deposits (SOD) data. These data that provide information on the number of branches of each bank in a county. We combine \widetilde{IT}_b with the branch network of each bank in 1999, thus prior to the period of analysis. The average IT adoption of all banks present in a county is defined as:

$$IT\ exposure_c = \sum_{b=1}^N \widetilde{IT}_b * \frac{No.\ branches_{b,c}}{No.\ branches_c}, \quad (13)$$

where $No.\ branches_{b,c}$ is the number of branches of bank b in county c in 1999 and $No.\ branches_c$ is the total number of branches across all banks in 1999 for which \widetilde{IT}_b is available. For the ease of interpretation, $IT\ exposure_c$ is standardized to a mean of zero and standard deviation of one. Higher values indicate that banks with branches in a given county have adopted relatively more IT.

Our main measure of IT adoption is based on the use of personal computers across bank branches in the United States, as the ratio of PCs per employee has not only the most comprehensive coverage, but has also been used extensively in the literature (Bresnahan et al., 2002; Brynjolfsson and Hitt, 2003; Beaudry et al., 2010; Bloom et al., 2012). That said, to examine the validity of our measure, we exploit additional information on banks' IT budget available in the 2016 vintage. The correlation between the IT budget of an establishment and the number of computers as a share of employees is 0.65 in 2016. There is also a strong positive correlation between PCs per employee and the probability of the adoption of cloud computing. These correlations provide assurance that the number of PCs per employee is a valid measure of IT adoption.

County and industry data. Data on young firms are obtained from the Quarterly Workforce Indicators (QWI), which provide detailed data on end-of-quarter employment at the county-two-digit NAICS industry-year level. Importantly, they provide a breakdown by firm age brackets. Detailed data are available from 1999 onward. QWI are the

only publicly available data set that provides information on county employment by firm age and industry.

We follow the literature and define young firms or entrepreneurs as firms aged 0–1 (Adelino et al., 2017; Curtis and Decker, 2018; Doerr, 2021). For each two-digit industry in each county, we use 4th quarter values. Note that the employment of young firms is a flow and not a stock of employment, as it measures the number of jobs created by new firms in a given year. In our baseline specification, we scale the job creation of young firms by total employment in the same county-industry cell, but results are unaffected by other normalization choices (see Section 6). Scaling young firm employment by total employment has the benefit that county or industry-specific shocks common to all firms within a county and/or sector will be cancelled out. There is significant variation in job creation rates by startups both across and within states, and entrepreneurial activity is high also outside of e.g. tech hubs such as the Silicon Valley.

The 2007 Public Use Survey of Business Owners (SBO) provides firm-level information on sources of business start-up and expansion capital, broken down by two-digit NAICS industries. For each industry i we compute the fraction of young firms out of all firms that reports using home equity financing or personal assets (*home equity* henceforth) to start or expand their business (Doerr, 2021). In addition, we collect information on the reported capital required to start a company in each industry. Following Rajan and Zingales (1998), we measure industry-level dependence on external finance as capital expenditure minus cash flow over capital expenditure, average over the decade prior to our sample period.

The US Department of Agriculture provides a list of land-grant colleges and universities that were established in the nineteenth century (1862 and 1890). Data on enrolment by major and test scores are obtained from the Integrated Postsecondary Education Data System survey for 1996.

County controls include the log of the total population, the share of the black population and the share of the population older than 65 years, the unemployment rate, house price growth, and the log of per capita income. The respective data sources are: Census Bureau Population Estimates, Bureau of Labor Statistics Local Area Unemployment Statistics, Federal Housing Finance Agency (FHFA) repeat sales House Price Index (HPI), and Bureau of Economic Analysis Local Area Personal Income.

Bank data. The Federal Deposit Insurance Corporation (FDIC) provides detailed bank balance sheet data in its Statistics on Depository Institutions (SDI). To construct bank-level controls, we collect second quarter data for each year on banks' total assets, Tier 1 capital ratio, non-interest and total income, total investment securities, overhead costs (efficiency ratio), non-performing loans, return on assets, and total deposits.

We further use Community Reinvestment Act (CRA) data on loan origination at the bank-county-year level, collected by the Federal Financial Institutions Examination Council at the subsidiary-bank level. CRA data contain information on loans with commitment amounts below \$1 million originated by financial institutions with more than \$1 billion in assets. We aggregate the data to the BHC-county level and then compute loan growth as log differences. We also compute loan growth for loans of origination amount smaller than \$100,000.

Descriptive statistics. In the average county, the employment share of entrepreneurs out of total employment equals 5.4%, with a standard deviation of 1.8%. At the county-industry level, mean and standard deviation average 5.6% and 4.5%. These numbers are in line with the aggregate employment share of young firms from 1999 to 2007, which stands at 4.7%. The IT variable has by definition a mean of 0 and a standard deviation of 1. It ranges from -2.6 to 2.6 with a median of -0.1 and an interquartile range from -0.5 to 0.5 . [Table 1](#) reports further summary statistics of variables at the county and bank level. [Table 2](#) further reports the balancedness in terms of beginning-of-sample county-level covariates, where we split the sample into counties in the bottom and top tercile of IT exposure. Except for population, we do not find significant differences across counties. Counties with high and low exposure to IT banks are similar in terms of their industrial structure, but also in terms of the IT adoption of non-financial firms in the county. The absence of a correlation between IT exposure to banks and most other county-specific variables is reassuring as it suggests that counties' exposure to IT in banking is also uncorrelated with other unobservable county characteristics that could bias our results.

4 IT Exposure and Entrepreneurship

This sections proposes a set of empirical tests at the county level for the main predictions of the model described in [Section 2](#) and provides results.

4.1 IT exposure and entrepreneurship (Prediction 1)

Prediction 1 implies a positive relation between the share of high-IT banks in a market and local entrepreneurial activity. To test this prediction, we estimate the following cross-sectional regression at the county-industry level:

$$\begin{aligned} \text{startups}_{c,i} = & \beta_1 \text{IT exposure}_{c,99} + \beta_2 \text{constraint}_i \\ & + \beta_3 \text{IT exposure}_{c,99} \times \text{constraint}_i + \text{controls}_{c,99} + \theta_c + \phi_i + \varepsilon_{c,i}. \end{aligned} \tag{14}$$

The dependent variable is the employment share of firms of age 0-1 (startups) out of total employment in each county (c) and 2-digit industry (i), averaged over 1999-2007. *IT exposure_c* denotes county exposure to IT-intensive banks as of 1999, measured by the IT adoption of banks' historical presence in the county. The variable *constraint_i* captures industry-level dependence on external finance. Standard errors are clustered at the county level, and regressions are weighted by total employment.

The relationship between IT exposure and local entrepreneurship could be driven by observable or unobservable local characteristics. To mitigate this concern, we include a rich set of county-level controls, all as of 1999. By controlling for county size (log of the total population) we avoid comparing smaller rural counties to larger urban ones. We further control for the share of the population of age 65 and older, as younger individuals may be more likely to start companies and also have better IT knowledge (Ouimet and Zarutskie, 2014; Bernstein et al., 2021). Similarly, we control for the share of adults with a bachelor degree or higher. Other socio-demographic controls, such as the share of the black population, the unemployment rate, and household income, purge our estimates from a potential correlation between local income or investment opportunities and the variables of interests. We also control for differences in the industrial structure of counties (proxied by employment shares in the major 2-digit SIC industries 23, 31, 44, 62, and 72). Finally, we control for IT in non-financial firms (measured as the average PCs per employee in non-financial firms) to address the concern that startup activity may thrive in location where IT is more readily available in general. As discussed further below, we also enrich the specification with granular fixed effects.

Abstracting from interaction terms, **Prediction 1** implies that $\beta_1 > 0$. Before moving to the regression analysis, panel (a) in Figure 1 shows a significant positive relationship between IT exposure and startup employment. It provides a binscatter plot at the county level, with the share of employment among firms age 0–1 on the vertical axis and county

exposure on the horizontal axis. We now investigate this pattern in greater detail.

Table 3 shows a positive relation between county IT adoption and startup activity. Column (1) shows that counties with higher levels of IT exposure also have a significantly higher share of employment among young firms. Column (2) shows that the coefficient declines only slightly in magnitude when we add county-level controls, while the R-squared increases more than ten-fold. Column (3) adds industry fixed effects to control for unobservable confounding factors at the industry level. Including these fixed effects does not change the coefficient of interest in a statistically or economically meaningful way, despite a sizeable increase in the R-squared by 20 pp. The stability of the coefficient in light of the increase in R-squared suggests that the effect of counties' IT exposure on job creation by startups is orthogonal to observable county and unobservable industry characteristics, reducing potential concerns about self-selection and omitted variable bias (Altonji et al., 2005; Oster, 2019).

The economic magnitude of the estimated effect is sizeable: In column (3), a one standard deviation higher IT exposure is associated with a 0.37 pp increase in the share of young firm employment (7% of the mean). While the employment share of young firms has declined steadily (Decker et al., 2016) – by around 3 pp since the 1990s – these results suggest that banks' IT adoption partly offset this trend.

In the model, IT spurs entrepreneurship through a relaxation in firms' borrowing constraints. We thus expect the positive correlation in columns (1)–(3) to be stronger in industries that depend more on external finance. We therefore augment the regression with an interaction term between IT adoption and industry-level dependence on external finance (β_3 in Equation (14)). In column (4), the coefficient on the interaction term between IT exposure and external financial dependence is positive and statistically significant. Counties with higher IT exposure have a higher share of employment among young firms precisely in those industries that depend more on external finance, consistent with the notion that the correlation is driven by the impact of banks' IT on startups' financing. In column (5), we further enrich our specification with county fixed effects to control for any observable and unobservable confounding factors at the local level. Results are near-identical to column (4): the inclusion of county fixed effects changes the estimated impact of IT exposure interacted with financial dependence by only 0.02 pp – despite the fact that the R-squared increases by 10 pp. This finding suggests that unobservable county factors are unlikely to explain the relationship between entrepreneurship and IT exposure.

To interpret the magnitude, column (6) replicates column (4), but uses a dummy with a value of one if an industry lies in the top tercile in terms of external financial dependence. One standard deviation higher IT exposure is associated with a 0.22 pp increase in the share of young firm employment in industries that depend less on external finance, but a 0.68 pp increase in industries that depend more on external finance (13% of the mean).¹⁰

Taken together, [Table 3](#) provides support for **Prediction 1**: A larger local presence of IT-intensive banks is associated with more startup activity. This is especially so in sectors that depend more on external financing, suggesting that the relationship is driven by better access to credit.

Robustness. To show that the relation between IT exposure and entrepreneurship is robust, we perform a series of additional tests in [Table A3](#), discussed in more detail in [Section 6](#) below. We show that our results are insensitive to an alternative construction of IT exposure based on either the unweighted average of the IT adoption of banks that operate in a county, or the share of local deposits. Further, excluding firms in the financial and education industries, or individual regions that have particularly high IT exposure or entrepreneurial activity, does not affect our results. Excluding the top 20 counties in terms of venture capital (VC) funding activity (which receive almost 80% of total VC funding) yields results similar to our baseline. Similarly, normalizing the share of employment in startups by the previous year’s total employment to rule out our results are driven by the denominator leaves our conclusion unaltered. We also show that our main findings are present in tradable industries, which are less affected by local economic conditions. We also investigate the increase in IT adoption over time. We find that counties more exposed to the *increase* in IT in banking also experienced relatively higher *growth* in startup rates.

We further augment [Equation 14](#) with a set of controls for counties’ exposure to bank characteristics. That is, for all banks in our IT data, we compute a set of characteristics to capture bank profitability, funding and assets structure, size, and capitalization (capital ratio, return on assets, return on equity, wholesale funding ratio, deposit ratio, log assets, securitization ratio). We then project these characteristics on US counties by relying on banks’ historical footprint, as we do for IT. We find that the relationship between

¹⁰We also re-estimate [Equation 14](#) including only industries in the bottom half or bottom quartile of the external dependence index. We find a positive—but smaller and insignificant—correlation between entrepreneurship and exposure to IT in banking.

exposure to bank IT and entrepreneurship is unchanged by the inclusion of these controls (see [Table A7](#)), mitigating the concern that this finding is spuriously driven by correlation with other bank factors.

4.2 IT, collateral, and entrepreneurship (Predictions 2 & 3)

Predictions 2 & 3 of the model state that *i*) higher collateral values increases startup activity, and *ii*) they do so especially in counties with higher IT exposure. The role of collateral in our model is directly motivated by a large literature that highlights the importance of rising house prices for employment among small and young firms: Higher real estate prices increase collateral values and thereby mitigate informational frictions and relax borrowing constraints for constrained firms ([Rampini and Viswanathan, 2010](#); [Adelino et al., 2015](#); [Schmalz et al., 2017](#); [Bahaj et al., 2020](#)). It also builds on evidence that IT facilitates real estate appraisal and the transmission of associated information ([Kummerow and Lun, 2005](#); [Sawyer et al., 2005](#)).

We test these predictions by examining how local IT exposure affects the sensitivity of entrepreneurship to changes in house prices, using a county-industry-year panel from 1999 to 2007. We estimate the following regression:

$$\begin{aligned} \text{startups}_{c,i,t} = & \gamma_1 \text{IT exposure}_{c,99} + \gamma_2 \Delta HPI_{c,t} \\ & + \gamma_3 \text{IT exposure}_{c,99} \times \Delta HPI_{c,t} \\ & + \text{controls}_{c,t-1} + \theta_{c,i} + \tau_t + \varepsilon_{c,i,t}. \end{aligned} \tag{15}$$

The dependent variable is the employment share of firms of age 0-1 out of total employment in county (*c*) and 2-digit industry (*i*) in year (*t*). IT exposure_c denotes counties' IT exposure as of 1999. $\Delta HPI_{c,t}$ is the yearly county-level growth in house prices. Controls include county size (log of total the population), the share of the population of age 65 and older, the share of the black population, education, the unemployment rate, the industrial structure, and IT adoption among non-financial firms, all lagged by one period. Standard errors are clustered at the county level, and regressions are weighted by total employment.

[Table 4](#), column (1) confirms that higher IT exposure is associated with a higher share of young firm employment. This is in line with results in [Table 3](#) on **Prediction 1** ($\gamma_1 > 0$). We then explicitly test **Prediction 2**, which implies that $\gamma_2 > 0$. Column (2) shows that a rise in house prices is associated with an increase in entrepreneurship at

the local level, conditional on year fixed effects that absorb common trends.

We then test **Prediction 3** by including the interaction term between changes in local house prices and county exposure to IT in banking (γ_3). Based on **Prediction 3**, we expect $\gamma_3 > 0$, i.e. an increase in house prices leads to an increase in startup-activity especially in counties more-exposed to IT. Column (3) shows that higher house prices spur entrepreneurship in areas with more IT, consistent with **Prediction 3**. [Figure 2](#) plots the estimated effect of house prices growth on entrepreneurship for low, medium and high IT counties. In the average county in terms of bank IT adoption, there is a positive relationship between higher house price growth and entrepreneurship (indicated by the green line) consistent with the positive coefficient on IT adoption itself. The red line plots the same relationship between house price growth and entrepreneurship for a county where bank IT adoption is two standard deviations above the mean and, as a result of the positive interaction term between IT and house price growth, the slope is steeper relative to the average county. For counties where IT adoption of banks is two standard deviations below the mean, changes in house prices are not estimated to have a significant effect on entrepreneurship (blue line). Moreover, the graph illustrates the even when zeroing in on counties where house prices fell during our sample period, job creation by young firms was stronger in high IT compared to lower IT regions. Overall, these results suggest that (i) IT adoption, for both low and high house price growth, helps entrepreneurship, and (ii) strong house price growth even in low IT areas does not seem to harm job creation of young firms.

To isolate the variation of interest and controlling for any confounding factor at the local or industry level, we include county*industry fixed effects and exploit only the variation within each county-industry cell in column (4) of [Table 3](#). It confirms the more pronounced relationship between house prices and entrepreneurship in areas with more IT. To further tighten identification, columns (5) and (6) add time-varying county controls, as well as industry*year fixed effects that account for unobservable changes at the industry level. The interaction coefficient remains similar in terms of sign, size and significance. In terms of magnitude, suppose house price growth increases from the 25th percentile (2.5%) to the 75th percentile (6.7%). In counties with an IT exposure of one, the share of employment at young firms would increase by 0.287 p.p. more per year than in counties with an IT exposure of zero (0.303 vs 0.016, based on column (3)). Note that IT exposure is standardized to a standard deviation of one.

Finally, we provide complementary evidence on the role of collateral, building on

previous work demonstrating that the importance of real estate collateral differs across industries. Specifically, young firms have been shown to be more responsive to changes in collateral values in industries in which the average required start-up capital is lower, or in industries in which a larger share of entrepreneurs relies on home equity to start or expand their business (Adelino et al., 2015; Doerr, 2021). Focusing on differences between industries within the same county and year also allows us to additionally include county*year fixed effects. We thus purge our estimates from the impact of any time-varying county-level shocks, in addition to controlling for industry-specific trends. Columns (7) and (8) show that the positive effect of rising house prices on startups in more-IT exposed counties is especially pronounced in those industries whose financing is expected to be more sensitive to changes in collateral values, as indicated by the positive and significant coefficient on the triple interaction term. Note that the remaining coefficients are absorbed by fixed effects.

In sum, Table 4 provides evidence in line with **Predictions 2 & 3**: entrepreneurship increases when local collateral values rise, and in particular so in counties with higher exposure to IT-intensive banks.

4.3 IT exposure and startup quality (Prediction 4)

Prediction 4 states that higher startup activity due to IT exposure does not lower the quality of the average firms receiving funding in equilibrium. As IT improves the screening process, there is no trade off between the quantity of credit and the marginal quality of the borrower.

In the model firm quality is disciplined by the probability of default, which is unobservable in the data. Instead, we proxy startup quality with the average growth rate of employment of startups during their first years of life. To this end, we construct ‘transition rates’ (Adelino et al., 2017). As the QWI report employment of firms of eg age 0–1, 2–3, or 4–5 in a given year, we can subtract the employment of startups (firms age 0 or 1 year) two years earlier from employment of firms of age 2–3 to obtain the change in jobs created by continuing startups during that period. The transition rate in a county-industry cell is thus defined as $transition_{c,s,t}^{2-3} = \frac{Employment\ Age\ 2-3_{c,s,t+2} - Employment\ Startup_{c,s,t}}{Total\ Employment_{c,s,t}}$ in year t . We construct similar transition rates for firms transitioning from age 2–3 to 4–5.

We then estimate a cross-sectional regression similar to Equation 14, where the dependent variable is the average transition rate between 1999 and 2007. Columns (1)-(3)

in [Table 5](#) show that there is no systematic correlation between a county’s exposure to IT in banking and the transition rates of local startups to age 2–3, neither on average nor in industries that are more dependent on external finance. We find similar effects for the transition rates for firms of age 2–3 years to 4–5 years in columns (4)-(6). These results lend support to **Prediction 4**.

The absence of any significant relationship between IT exposure and local startup quality could suggest that IT adoption by banks has aggregate implications. The formation of more startups, without a decline in quality, could bring benefits in terms of aggregate business dynamism, employment and productivity growth ([Haltiwanger et al., 2014](#); [Klenow and Li, 2020](#)).

4.4 The role of recourse default (**Prediction 5**)

Recourse can partially substitute for the need of screening borrowers through collateral. The ability to recourse in the case of foreclosure or default thus diminishes the misalignment of interests ([Ghent and Kudlyak, 2011](#)). In the model, **Prediction 5** thus implies that the positive relationship between IT exposure and entrepreneurship is more pronounced in non-recourse states. To test this prediction, we exploit heterogeneity across US states in terms of legal and practical considerations that make obtaining a deficiency judgment more or less difficult for lenders. We follow [Ghent and Kudlyak \(2011\)](#) to classify recourse and non-recourse states according to whether they allow, at least in some cases, deficiency judgment. We then estimate the cross-sectional relationship between IT and entrepreneurship (i.e. [Equation 14](#)) for counties in recourse versus non-recourse states.¹¹

Columns (1) and (2) in [Table 6](#) highlight that the positive relationship between IT exposure and job creation by startups is stronger in non-recourse states, in line with the model’s prediction. We confirm this finding in interaction specifications in columns (3) and (4). Column (3) shows that in recourse states the relationship between IT adoption and entrepreneurship is significantly weaker. Column (4) confirms the finding when we exclude North Carolina, as its classification presents some ambiguity. Moreover, we find that the sensitivity of entrepreneurship to changes in house prices – which is generally higher in counties with higher IT exposure – is lower in recourse states (see column (9))

¹¹[Ghent and Kudlyak \(2011\)](#) relies on recourse / non-recourse classifications of states from the 21st edition (2004) of the National Mortgage Servicer’s Reference Directory to show that recourse clauses impact borrowers’ behavior.

in [Table 4](#)).

5 Banks' IT adoption and Small Business Lending

In this section, we use CRA data on banks' small business lending in each county to provide additional tests of the model predictions. We first investigate **Prediction 6**, i.e. that with increasing IT adoption, lending becomes more responsive to new investment opportunities in more-distant counties. We then revisit **Predictions 2 & 3** on the importance of collateral values in stimulating lending and job creation. An advantage of bank-county level regressions is that we can measure IT adoption directly at the bank-level. This setting allows us to combine an instrumental variable approach with granular county fixed effects. We can thus exploit exogenous variation in the IT adoption of banks that lend to borrowers in the same county.

5.1 Land-grant colleges and banks' IT adoption

The established relationship between IT adoption and bank lending could be driven by unobservable factors. For instance, banks may invest more in IT to serve certain customers; other factors, such as local productivity shocks, may drive both banks' adoption and credit demand. Studying directly the relationship between a bank's lending and its IT adoption, rather than through geographic variation in banks' footprints, allows us to obtain exogenous variation in IT-adoption through an instrumental variable. Specifically, we exploit the quasi-random allocation of land-grant colleges, which acted as a shift in the availability of local technical expertise ([Moretti, 2004](#)) and has been shown to predict banks' IT adoption ([He et al., 2021](#); [Pierri and Timmer, 2022](#)). The Morrill Act of 1862, and its follow-up in 1890, endowed states with federal land to found universities, with a focus on teaching science, agriculture, and other technical subjects. The presence of a land-grant college remains an important determinant of the supply of skilled labour in a city even today, especially for the IT sector. Their exact location, however, is largely due to historical accidents and close to random from today's perspective ([Moretti, 2004](#)). It is also unrelated to current local economic factors ([Kantor and Whalley, 2019](#)), as well as to the presence of banks' HQ in the same county ([Pierri and Timmer, 2022](#)), reflecting that the formation of banks' headquarters usually predates the IT revolution by many decades.

Land-grant colleges could spur banks' IT adoption through different channels. They directly increase the supply of tech-inclined graduates that banks could hire, which could incentivize their IT adoption. Additionally, a lower distance to campuses could lead to knowledge spillovers and the diffusion of ideas and technology (Keller, 2002), making bank managers more likely to invest in IT. As decision-making at a firm is often driven by its HQ, we base our instrument on the distance of a bank's HQ to the nearest land-grant colleges. In a first step, we compute the distance in log miles (plus one) between the county of each land-grant college j and a bank's HQ county, weighted by the size of the college in terms of STEM enrollment. In a second step, we compute a measure of the average distance to land-grant colleges. There is no clear economic reason to expect why the distance to only the nearest, second- or third-nearest college should matter. In addition, distances to the nearest colleges are positively correlated. We thus take an agnostic approach and take the first principal component of the distance to the nearest two land-grant colleges as our baseline instrumental variable, so the IV captures only the salient variation in distances. We also compute the first principal component of the distance to the nearest three or five colleges for robustness tests.

The key identification assumption underlying our instrument is that the distance to the nearest land-grant colleges affects the ability to lend to small businesses through banks' IT adoption, and not through other bank-specific channels or changes in the demand for credit. Students of land-grant colleges are significantly more likely to major in technical subjects and less likely to major in business and management sciences (Pierri and Timmer, 2022). The introduction of these colleges is thus akin to a shifter of the availability of local technical knowledge for banks, rather than overall managerial capabilities. It mitigates the concern that the impact of IT adoption is capturing better managerial practices (Bresnahan et al., 2002).

As expected, we find a strong negative association between the distance to the nearest land-grant colleges and banks' IT adoption (see Figure 3, panel a). Further, in regressions we control for an extensive set of bank-level controls – most importantly bank size, which is commonly associated with economies of scale that could facilitate IT adoption. As panel (b) of Figure 3 shows, the strong relation between distance to the nearest land-grant colleges and IT adoption remains when we condition on bank size (log assets).

Land-grant colleges could also affect non-financial firms in close proximity by increasing the availability of technical knowledge, thereby directly affecting entrepreneurship and credit demand. Therefore, we compare the lending of *different banks*—those HQ have dif-

ferent distance to land-grant colleges—to borrowers *in the same county*. To do so, we include in our specifications fixed effects at the borrower-county level (discussed below). These fixed effects absorb all potentially confounding factors that affect local credit demand by non-financial firms, including local technology adoption and human capital availability. We furthermore exclude the HQ county of each bank, as well as counties with land-grant colleges, from the sample.

5.2 IT and the role of distance in lending (Prediction 6)

In the model, IT lowers the cost of banks to verify the existence and market value of collateral, and transmit the information to their (distant) HQ. This mechanism is consistent with work that suggests that IT adoption by banks reduces the importance of distance in lending decisions, as it enables a more effective transmission of hard information (Petersen and Rajan, 2002; Vives and Ye, 2020).

Prediction 6 thus states that with increasing IT adoption, lending should become more responsive to new investment opportunities in more distant counties. Following a large literature that shows that informational frictions increase with lender-borrower distance (Liberti and Petersen, 2019), we test whether the relationship between local investment opportunities and lender-borrower distance varies with banks’ use of IT. We consider the following specification from 1999 to 2007 at the bank-county-year level:

$$\begin{aligned} \Delta loans_{b,c,t} = & \beta_1 \log(distance)_{b,c} + \beta_2 \Delta income\ p.c._{c,t} \\ & + \beta_3 \log(distance)_{b,c} \times \Delta income\ p.c._{c,t} \\ & + controls_{c/b,t-1} + \theta_{c,t} + \varepsilon_{b,c,t}, \end{aligned} \tag{16}$$

if IT = low/high.

The dependent variable is the log difference in total CRA small business lending by bank b to borrower county c in year t . The variable $\log(distance)$ measures the log of the distance between banks’ HQ county and the county of the borrower. We proxy investment opportunities in borrower countries with the log change in county-level income per capita (Adelino et al., 2017). Regressions further include standard county controls, as well as year or county*year fixed effects. Bank-level controls are the log of total assets, deposits over total liabilities, the share non-interest income, securities over total assets, return on assets, the equity ratio (Tier 1), and the wholesale funding ratio. We also control for the share of C&I out of total loans, as well as the share of mortgage loans out of

total loans. We thus hold the allocation of lending of credit *across* lending segments constant. Standard errors are clustered at the bank and county level. An increase in local investment opportunities is expected to increase local lending ($\beta_1 > 0$), especially in borrower counties nearer to the HQ ($\beta_3 < 0$). If banks' IT adoption reduces the importance of distance, then β_3 should be significantly smaller in magnitude for *high IT* banks.

Results in [Table 7](#) are in line with the hypotheses. Column (1) shows that rising local incomes are associated with higher local loan growth. Greater distance reduces the sensitivity of banks' small business lending in response to local investment opportunities, as the interaction terms between changes in income and distance is negative. This findings holds when we include county*year fixed effects to control for any unobservable time-varying borrower-county characteristics in column (2). Columns (3) and (4) show that the lower responsiveness of bank lending in counties located further away is present only among low IT banks; for high IT banks, distance has no dampening effect.

An interaction specifications in column (5) confirms this finding: While distance reduces the sensitivity of lending to changes in local investment opportunities for low IT banks, among high IT banks distance matters significantly less. Results are similar when we focus on total lending through loans with origination amounts below \$100,000, which are usually granted to smaller companies. Note that coefficients increase in magnitude, which is consistent with the common finding that informational frictions are more severe among smaller firms.

Finally, columns (7)–(8) replicate columns (5)–(6), but instrument banks' IT, as well as the associated interaction terms, with the IV based on distance to the nearest two land-grant colleges. The main coefficients are similar in terms of sign and significance, but larger in magnitude. This mostly reflects that the standard deviation in IT when predicted with land-grant colleges is around 0.15 times as large as variation in actual IT adoption (0.156 vs. 1). Hence, when we adjust for the difference in standard deviations across actual and predicted IT, coefficients are similar in magnitude in columns (5)–(6) vs. (7)–(8). A larger magnitude of the IV coefficients can also be due to the measurement error of the endogenous IT adoption variable. As our measure of IT adoption is built from the ratio of computers per employee, it does not take into account differences across IT applications, it does not capture heterogeneous quality of IT equipment, nor it considers workers' different ability of using such equipment. We therefore expect a significant amount of noise, and it is unsurprising that IV coefficients are larger than OLS ones.

As discussed above, the regressions include county*time fixed effects and hence absorb unobservable changes at the borrower-county level. This approach strengthens our identification assumption, as these fixed effects control for potentially confounding factors that could be correlated with the local presence of land-grant colleges, and hence the demand for credit. In the appendix, we show that our results are insensitive to using an IV based on distance to the three or five nearest land-grant colleges, or when we exclude banks' HQ counties (see [Table A6](#)).

5.3 IT, house prices and small business lending

We now revisit **Predictions 2 & 3** to provide supporting evidence that banks' IT improves access to finance for entrepreneurs, especially when house prices increase. To this end, we investigate how high- and low-IT banks adjust their small business lending in response to house price changes. We estimate the following regression equation from 1999 to 2007 at the bank-county-year level:

$$\begin{aligned} \Delta loans_{b,c,t} = & \beta_1 IT_b + \beta_2 \Delta HPI_{c,t} + \beta_3 IT_b \times \Delta HPI_{c,t} \\ & + bank\ controls_{b,t-1} + county\ controls_{c,t-1} + \tau_t + \varepsilon_{b,c,t}. \end{aligned} \tag{17}$$

The dependent variable is the growth in total CRA small business lending by bank b to borrower county c in year t . The main explanatory variable IT_b measures the use of IT at the bank level, as described in [Section 3](#). $\Delta HPI_{c,t}$ measures the yearly change in house prices in the borrower county. County and bank controls are the same as in [Equation 16](#). We cluster standard errors at the bank and county level. If IT-intensive banks rely more on hard information when lending to opaque firms, as indicated by the county-level analysis in [Section 4](#), we expect their lending to be more sensitive to changes in local collateral values, i.e. house prices ($\beta_3 > 0$).

[Figure 4](#) suggests that while small business lending grows faster when house prices increase, the sensitivity is higher for lending of IT-intensive banks. Results in [Table 8](#) confirm this pattern. Column (1) shows a larger responsiveness of small business lending by high-IT banks to rising house prices, as indicated by the significant coefficient on the interaction term. Since borrower counties could differ along several dimension, we enrich our specifications with time-varying fixed effects at the county level in column (2). We now essentially compare small business lending by two banks that differ in their IT intensity to borrowers in the *same* county, mitigating concerns that the relation between

bank lending and house prices is due to (unobservable) confounding local factors. Results show that despite a more than fourfold increase in the R-squared, estimated coefficient estimates remain near-identical (the coefficient on the change in house prices is now absorbed). Columns (3)–(4) repeat the exercise for loans of size \$100,000 or less and show similar results. Again, magnitudes are larger, indicating that smaller firms are subject to greater informational frictions and their financing conditions hence more sensitive to changes in collateral values.

Instrumental variable regressions in columns (5)–(6) confirm this finding. Higher IT adoption by banks leads to a greater sensitivity of small business lending to local house prices. By including county*time fixed effects we control for county-level characteristics that could correlate with the distance to land-grant colleges. Similar to above, when we adjust for the difference in standard deviations across actual and predicted IT, IV coefficients are similar in magnitude to their OLS counterparts. As we show in the appendix, these patterns are robust to using an IV based on distance to the three or five nearest land-grant colleges, or when we exclude banks’ HQ counties (see [Table A6](#)).

6 Collateralized Lending, Competition, and Further Tests

In this section we present additional evidence that speaks to assumptions and implications of the model, as well as further robustness tests. We report the results in the Online Appendix.

IT and the use of collateral. A key assumption of the model is that high IT banks have a relative cost advantage in screening through collateral. While we do not have loan-level information on collateralized lending to startups, we can provide empirical evidence on the presence of collateral for large corporate loans with data from DealScan ([Ivashina and Scharfstein, 2010](#)). [Figure A1](#) shows that the share of loans that are collateralized is positively correlated with bank IT adoption. To ensure that this correlation is not driven by (unobservable) borrower heterogeneity, we estimate the following linear probability model:

$$secured_{b,i,t} = \beta IT_b + \tau_t + \theta_i + \varepsilon_{b,i,t}, \quad (18)$$

where b denotes a bank that granted a loan in year t to corporate borrower i and $secured_{b,i,t}$ is a dummy equal to one whenever the loan is collateralized. Results in [Table A1](#) confirm that more IT-intensive banks are more likely to require collateral than other banks, even when controlling for borrower characteristics through borrower fixed effects.

The role of local competition. The model abstracts from interactions between local competition and IT adoption in the banking sector. Instead, banks and borrowers share the surplus from lending if a loan is granted. To ensure that local competition does not affect our key empirical results, we re-estimate [Equation 14](#), but control for market concentration (measured through the HHI) and its interaction with IT. Results are presented in [Table A2](#), where columns (1)–(2) construct the HHI from CRA loan shares and columns (3)–(4) from deposit shares. In general, higher concentration is associated with higher startup activity. This could reflect that lenders in less competitive markets have a sufficiently high surplus to acquire costly soft information or that they might be more prone to lend to startups because know they expect to extract more surplus in the future as young firms grow ([Petersen and Rajan, 1995](#)). However, there is no significant interaction between concentration and local IT adoption in banking, and the positive impact of IT on startups remains largely unaffected when we account for the local market structure. This result supports the model’s assumption to abstract from local competition.

Extensions and robustness. [Table A3](#) presents robustness tests to our main results at the county level. Column (1) replicates the baseline result for comparison (see column (3) in [Table 3](#)). In column (2), IT exposure is the unweighted average of the IT adoption of banks that operate in a county and in column (3) exposure is weighted by the share of local deposits (rather than the number of branches). The positive association between IT exposure and entrepreneurial activity remains, highlighting that it is not driven by any specific choice of the construction of the IT exposure measure. Column (4) excludes employment in startups in the financial and education industries and column (5) excludes Wyoming, the state with the highest exposure to banks’ IT adoption. Results remain unaltered. Column (6) includes state fixed effects and shows that results are also present when we exploit within-state variation only. Column (7) normalizes the share of employment in startups by the previous year’s total employment to rule out that our results are driven by a decline in total employment instead of an increase in young firms’ employment. In fact, column (8) shows that IT positively but insignificantly affects total

employment, suggesting that the employment growth in young firms can promote total job growth, but as young firms are mostly small when founded, the effect is likely to weak to make a strong contemporaneous economic and statistical impact on total employment. our results are not driven by a decline in total employment. Column (9) focuses in firms in tradable industries, which are less affected by local economic conditions.¹² Finally, columns (10) and (11) address the concern that the availability of other forms of external financing, venture capital (VC) in particular, may be correlated with IT exposure. As VC funding is highly concentrated in a small fraction of the US territory, we exclude the top 20 counties (representing almost 80% of VC funding at the time) or seven states with the highest VC activity,¹³ and find results similar to baseline.

Increase in IT adoption over time. An alternative approach to test **Prediction 1** is to analyze the relationship between the *increase* in IT adoption and *changes* in entrepreneurship at the county-level. To do so, we compute the change in county exposure as

$$\Delta IT_c = \sum_{b=1}^N \Delta \widetilde{IT}_b * \frac{No. Branches_{b,c}}{No. Branches_c}, \quad (19)$$

where $\Delta \widetilde{IT}_b$ is the increase of IT adoption between 1999 and 2006 of bank b . We find that counties more exposed to an increase in IT in banking also experienced stronger performance of startups, as illustrated by panel (b) in [Figure 1](#). The positive correlation between changes in IT adoption in banking and changes in startup rates is also confirmed by more formal regression analysis presented in [Table A4](#). Note that this first-difference approach implicitly controls any county-level (time invariant) observable and unobservable characteristics.

Minority Entrepreneurship. Our results indicate that IT increases the importance of real estate collateral in lending decisions, which could suggest that entrepreneurs with insufficient personal or family wealth may not be able to benefit to the same extent as others. Previous research has shown that some communities, such as racial and ethnic minorities, have experienced long lasting discrimination in the mortgage market ([Munnell et al., 1996](#)) and have thus been accumulated less real estate wealth. Minority entrepreneurs also face more hurdles in access to capital ([Fairlie et al., 2020](#)).

¹²We rely on the tradable classification of 4 digit industries by [Mian and Sufi \(2014\)](#), which we aggregate to the 2 digit level.

¹³See e.g. <https://pitchbook.com/newsletter/28-counties-account-for-80-of-vc-investment-in-the-us>.

The QWI report employment by race, but not the race of the entrepreneur. To the extent that entrepreneurs are likely to hire from their personal networks or job referral are more likely among people of the same ethnic or racial group, startups with a larger share of black employees are more likely to be owned by a black entrepreneur. We therefore investigate the relationship between IT in banking and the share of startups' employees that are black within a county, normalized by subtracting the same share for white employees. [Table A5](#) reveals that counties more exposed to IT in banking have a lower share of black employees among startups. This result suggests that IT adoption in banking fosters entrepreneurship and business dynamism in general, but may perpetuate inequality across demographic groups.

7 Conclusion

Over the last decades, banks have invested in information technology at a grand scale. However, there is little evidence on the effects of this IT revolution in banking on lending and the real economy. In this paper we focus on the effects of banks' IT adoption on startups, and do so for two reasons. First, startups matter greatly for aggregate employment, innovation, and growth; and second, they are opaque borrowers and hence likely to be especially sensitive to technologies that affect lenders' information acquisition.

We find that IT adoption in the financial sector has spurred entrepreneurship. In regions where banks with higher IT-adoption have a larger footprint, job creation by startups was relatively stronger. This relationship is particularly pronounced in industries that rely more on external finance. We show – both theoretically and empirically – that collateral plays an important role in explaining these patterns. As IT makes it easier for banks to assess and transmit the value and quality of collateral, banks with higher IT adoption lend more against increases the value of entrepreneurs' collateral.

Our results have implications for policy. Banks have been ardent adopters of technology during the last years. Meanwhile the role of FinTech companies that rely on technology and algorithms, rather than loan officers, to provide credit to small businesses has been steadily increasing ([Gopal and Schnabl, 2021](#)). These developments have triggered a debate on the impact of IT adoption in financial sector on the real economy, for example through its impact on the relative importance of soft and hard information, or the need for collateral ([Gambacorta et al., 2020](#)). Our findings suggest that IT adoption can spur job creation by young firms by making lending against collateral, or hard infor-

mation more general, easier. From a policy perspective, this finding raises the prospect that the rising adoption of financial technology in the financial sector eases financial constraints for young and dynamic firms.

Figures and Tables

Figure 1: Job creation by young firms and banks' IT adoption

Panel (a) shows a binscatter plot of the share of employment by young firms over total employment in a county-industry cell, averaged over the period from 2000 to 2007, on the vertical axis and county-level exposure to banks' IT adoption, as defined in Section 3, on the horizontal axis. Panel (b) shows a binscatter plot of the *change* in the startup rate in a county-industry between 2000 and 2007 (in percentage points) on the y-axis and the exposure of a county to banks' *change* in IT adoption between 2000 and 2007 (standardized) on the x-axis.

Figure 2: Job creation by young firms and house price changes

This figure plots the estimated effect of house price changes on job creation by young firms as a function of high (two standard deviation above mean) medium (mean) and low (two standard deviation below the mean) banks IT adoption counties.

Figure 3: Distance to land-grant colleges and IT adoption

Panel (a) shows a binscatter plot of banks' IT adoption on the vertical axis against the first principal component (FPC) of the distance of banks' HQ to the nearest two land-grant colleges on the horizontal axis. Panel (b) shows the same binscatter plot but conditional on bank size, measured via the log of total bank assets.

Figure 4: Banks' IT, house prices, and loan growth

This figure shows a binscatter of CRA loan growth on the vertical axis and county-level house price growth on the horizontal axis. The sample is split into banks above and below the median along the IT distribution. In a regression of CRA loan growth on house price growth ($\Delta CRA_{b,c,t} = \Delta house\ price\ growth_{c,t} + \varepsilon_{b,c,t}$), the respective coefficients (t-values) for high- and low-IT banks are 1.22 (5.93) and 0.30 (1.77).

Fixed Effects	Year	County \times Year	Year	County \times Year	County \times Year	County \times Year

This table reports results for regressions at the bank-county-year level (see Equation 17). The dependent variable is the change in total CRA loans by bank b to county c in year t or in CRA loans with an amount of less than \$ 100,000. IT_b is the IT adoption of bank b , $\Delta HPI_{c,t}$ is the yearly change in house prices in county c . Columns with header 'IV' refer to regression that instrument bank-level IT with the land-grant colleagues instrument. Standard errors are clustered at the bank and county level. The Kleibergen-Paap Wald F-statistics for all instrumented variables considered in columns (7) and (8) jointly equal 165.54 and 139.41. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$.

A1 Online Appendix

A1.1 Proofs

Recall from the discussion in the main text that only projects of high quality are funded in equilibrium irrespective of the type of bank, so Prediction 4 follows immediately. Thus, we can henceforth limit attention to firms with a good project.

Next, we construct the share of expected lending to young firms as a fraction of total expected lending, s_Y . All old firms with a good project are funded, which are of quantity $q(1 - y)$. Young firms with a good project, which are of measure qy , are funded when they meet a high-IT bank, which occurs with probability h , and when they have enough collateral $C > C_{min}$, which holds for a fraction $1 - G(C_{min})$ of these firms (all characteristics are independent). Thus, the measure of lending to young firms is $qyh[1 - G(C_{min})]$. Taken these points together, we obtain the share s_Y stated in Proposition 1.

The derivatives follow, where we use $\frac{dC_{min}}{dP} = -\frac{p_B}{1-p_B}(x - r)\frac{1}{P^2} < 0$ to sign them:

$$\frac{ds_Y}{dh} = \frac{y(1 - y)[1 - G(C_{min})]}{(1 - y + yh[1 - G(C_{min})])^2} > 0 \quad (20)$$

$$\frac{ds_Y}{dP} = \frac{y(1 - y)h}{(1 - y + yh[1 - G(C_{min})])^2} g(C_{min}) \left(-\frac{dC_{min}}{dP} \right) > 0 \quad (21)$$

$$\frac{d^2s_Y}{dh dP} = \frac{y(1 - y)(1 - y - yh[1 - G(C_{min})])}{(1 - y + yh[1 - G(C_{min})])^3} g(C_{min}) \left(-\frac{dC_{min}}{dP} \right) > 0, \quad (22)$$

where the sign of $\frac{d^2s_Y}{dh dP}$ arises from observing that $1 - y - yh[1 - G(C_{min})] \geq 1 - y - yh = 1 - y(1 - h) > 0$.

We turn to the case of recourse, where the no-recourse derivatives are unchanged:

$$\frac{ds_Y^R}{dh} = \frac{y(1 - y)(1 - i)[1 - G(C_{min})]}{(1 - y + y\{i + (1 - i)h[1 - G(C_{min})]\})^2} > 0 \quad (23)$$

We have $\frac{ds_Y^R}{dh} \rightarrow \frac{ds_Y}{dh}$ for $i \rightarrow 0$; since $i > 0$, this reduces the numerator and increases the denominator of $\frac{ds_Y^R}{dh}$ relative to $\frac{ds_Y}{dh}$, so $\frac{ds_Y^R}{dh} < \frac{ds_Y^{NR}}{dh} = \frac{ds_Y}{dh}$.

A1.2 Further Figures and Tables

Figure A1: Share of Secured Loans

This figure shows the share of secured loans in the Dealscan syndicated loan data and banks' IT adoption.

Cluster	County	County	County	County
HHI	CRA lending	CRA lending	FDIC deposits	FDIC deposits

This table reports results for the following regression: $startups_{c,i} = \beta IT\ exposure_{c,99} + \delta HHI_{c,99} + \gamma IT\ exposure_{c,99} \times HHI_{c,99} + controls_{c,99} + \phi_i + \varepsilon_{c,i}$, where $startups_{c,i}$ is defined as the share of the employees in county c and industry t which is employed at a firm with at most 1 year of life. The share is then averaged across the years 2000 and 2007. IT_c is the IT adoption of banks in the county, measured by the IT adoption of banks historically present in the county, and standardized with mean zero and a standard deviation of one. $HHI_{c,99}$ is the Herfindahl-Hirschman Index in county c , where market shares are computed from either small business lending in 1999 (from CRA data) or deposits in 1999 (from FDIC data). Standard errors are clustered at the county level. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$.

Cluster	County	County	County	County	County	County	County	County	County	County	County	County	County

This table reports results for the following regression: $startups_{c,i} = \beta IT\ exposure_{c,99} + controls_{c,99} + \theta_c + \phi_i + \varepsilon_{c,i}$, where $startups_{c,i}$ is defined as the share of the employees in county c and industry t which is employed at a firm with at most 1 year of life. The share is then averaged across the years 2000 and 2007. IT_c is the IT adoption of banks in the county, measured by the IT adoption of banks historically present in the county, and standardized with mean zero and a standard deviation of one. The Table report results from a set of robustness exercises. (1) Is the baseline regression. Column (2): local IT adoption is the unweighted average of the IT adoption of banks present in the county. In Column (3) we project bank IT adoption by the deposit share rather than the number of branches on the county. In column (4) we exclude finance and education as a sector. In (5) We exclude Wyoming. (6) We include state FE. (7) We divide employment creation of young firms by lagged total employment in the county sector cell. In Column (8) we use the change in total employment as a dependent variable. Standard errors are clustered at the county level. In (9) we restrict our sample to firms in tradable industries. In (10) and (11) we exclude high venture capital states and counties, respectively. In column (12) we control for the coverage. In (13) we exclude low coverage counties. *** p<0.01, ** p<0.05, * p<0.1.

Table A4: County IT exposure and Entrepreneurship - Long Differences

VARIABLES	(1)	(2)	(3)	(4)	(5)
	Δ share 0-1	Δ share 0-1	Δ share 0-1	Δ share 0-1	Δ share 0-1

Panel (a) reports results for regressions at the bank-county-year level (see Equation 16). The dependent variable is the change in total CRA loans by bank b to county c in year t or in CRA loans with an amount of less than \$ 100,000. IT_b is the IT adoption of bank b . $\Delta Income_{c,t}$ is the change in per capita income in county c between year $t - 1$ and t . $\log(distance)_{b,c}$ is the log of the number of miles between bank b 's headquarters and county c . $low/high$ IT refers to banks in the bottom/top tercile of the IT distribution. Panel (b) reports results for regressions at the bank-county-year level (see Equation 17). The dependent variable is the change in total CRA loans by bank b to county c in year t or in CRA loans with an amount of less than \$ 100,000. IT_b is the IT adoption of bank b , $\Delta HPI_{c,t}$ is the yearly change in house prices in county c . Columns with header 'no HQ' refer to regression that exclude banks' HQ county. Columns with header '2/3/5' use the first principle component of distance to the nearest two, three, or five land-grant colleges. Standard errors are clustered at the bank and county level. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$.

This table reports results from cross-sectional regressions at the county-industry level (see Equation 14). The dependent variable is the share of the employment in firms of age 0-1 in county c and industry i . $IT\ Exposure_c$ is the IT adoption of banks in the county, measured by the IT adoption of banks historically present in the county, and standardized with mean zero and a standard deviation of one. $Ext.\ fin.\ dep_i$ measures the dependence on external finance in an industry. Bank controls are county-level exposures (as defined for IT) to the following bank characteristics: capital ratio, return on assets, return on equity, wholesale funding ratio, deposit ratio, log assets, securitization ratio. Standard errors are clustered at the county level *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$.
