ARTICLE INFO

ABSTRACT

We examine the effect of ex-post information contagion on the ex-ante level of systemic risk defined as the probability of joint bank default. Because of counterparty risk or common exposures, bad news about one bank reveals valuable information about another bank, triggering information contagion. When banks are subject to common exposures, information contagion induces small adjustments to bank portfolios and therefore increases overall systemic risk. When banks are subject to counterparty risk, by contrast, information contagion induces a large shift toward more prudential portfolios, thereby reducing systemic risk.

1. Introduction

Systemic risk is the risk of joint default of a substantial part of the financial system, resulting in large social costs.[1] One major source of systemic risk is information contagion: when investors are sensitive to news about the health of the financial system, bad news about one financial institution can adversely spill over to other financial institutions. For instance, the insolvency of one money market mutual fund with a large exposure to Lehman Brothers spurred investor fears and led to a widespread run on all money market mutual funds in September 2008.[2] As information contagion affects various financial institutions including commercial banks, money market mutual funds, and shadow banks, we adopt a broad notion of financial intermediaries and call them banks for short.

An investor in one bank will find information about another bank's profitability valuable for two reasons. First, both banks may have common exposure to an asset class, such as risky sovereign debt or mortgage-backed securities. Learning about another bank's profitability helps investors assess the profitability of its bank (Acharya and Yorulmazer, 2008b). Second, a bank may have lent to another bank, for example to share liquidity risk (Allen and Gale, 2000). Learning about the debtor bank's profitability will help investors in the creditor bank assess its counterparty risk.

[1] The Bank for International Settlements (1997) compares the cost of systemic bank crises in various developing and industrialized countries and documents the range from about 3% of GDP for the savings and loan crisis in the United States to about 30% of GDP for the 1981–87 crisis in Chile.

[2] Lehman Brothers failed on September 15, 2008 and the share price of the Reserve Primary Fund dropped below the critical value of US$1 on September 16, 2008. See Brunnermeier (2009) for an overview.

We develop a model of systemic risk with information contagion based on classical banking models (Diamond and Dybvig, 1983; Allen and Gale, 2007). Our model features two banks, and systemic risk is defined as the probability of joint default. We contrast the cases with and without the arrival of information about the other bank. Due to counterparty risk or common exposures, bad news about one bank can trigger the default of another bank. Information contagion is the amount of a bank's additional fragility due to such bad news.

A key channel in our model is the effect of ex-post information contagion on the ex-ante choices of banks and the implied level of systemic risk. Banks in our model have three choices: the design of the demand-deposit contract (the interim-date withdrawal amount), the portfolio choice between liquid but low-return and illiquid but high-return assets, and the amount of interbank insurance against liquidity risk.

Since a closed-form analytical solution cannot be obtained in many economically interesting cases, we compute the equilibrium of the withdrawal game for any choice of parameters numerically. Our numerical algorithm is simple and robust. We discretize the choices of the bank in the first region. Then, we compute the best response of the bank in the second region and use it to compute the first bank's best response to the second bank's best response. If the first bank's best response equals the original portfolio choice, we have found an equilibrium allocation because of symmetry. We incur a small numerical error by discretizing the portfolio choice. However, this error becomes smaller as we refine the grid of portfolio choice variables. Our numerical results are confirmed for several interesting special cases for which we do obtain closed-form analytical solutions, thereby providing additional intuition to our model.

For a given ex-ante choice made by banks, information spillovers mechanically increase systemic risk. Once the portfolio choice adjusts given the potential of information contagion ex post, however, the effect of information contagion on systemic risk depends on the reason why information is valuable for investors. We obtain two results. First, the overall effect of information contagion due to common exposure is an increase in systemic risk (Result 1), which we label the *instability effect*.

Second, information contagion due to counterparty risk, by contrast, reduces systemic risk. Banks respond by making more prudent ex-ante choices to counteract ex-post information contagion. Banks choose to expose themselves less to counterparty risk by engaging in less liquidity co-insurance and hold more liquidity themselves. Overall, this reduces systemic risk (Result 2), which we label the *resilience effect*. The direct detrimental effect of information contagion on systemic risk is more than fully compensated for by an indirect beneficial effect via the ex-ante portfolio choice. Overall, systemic risk in the financial system is lower.

Taking these results together, the effect of information contagion on the level of systemic risk – via changes in banks' ex-ante choices in their portfolios and demand-deposit design – depend on the nature of the interbank linkage. While financial fragility increases when banks are linked via common exposure, financial fragility decreases when banks are linked via counterparty risk.

One of our contributions is to study information contagion due to counterparty risk and its effects on banks' ex-ante choices and systemic risk. Counterparty risk as a source of information contagion and its consequences for ex-ante choices have not been consistently studied before. Cooper and Ross (1998) and Ennis and Keister (2006) study the effect of ex-post individual bank runs on the ex-ante liquidity choice and the design of deposit contracts. By contrast, we analyze how information contagion due to counterparty risk affects banks' ex-ante portfolio choice and deposit contract design and examine the consequences for banks' joint default probability.

Our counterparty risk mechanism builds on the literature of financial contagion due to balance sheet linkages. Building on Diamond and Dybvig (1983) and Allen and Gale (2000) describe financial contagion as an equilibrium result.[3] Interbank lending insures banks against a non-aggregate liquidity shock and potentially achieves the first-best outcome. However, a zero-probability aggregate liquidity shock may spread through the entire financial system. While counterparty risk in our model also arises from the potential default on interbank obligations, we obtain the ex-ante portfolio choice since contagion may occur with positive probability.[4] Dasgupta (2004) also shows the presence of financial contagion with positive probability in the unique equilibrium of a global game version of Allen and Gale (2000), focusing on the coordination failure initiated by adverse information. By contrast, we study the impact of information contagion from counterparty risk on banks' ex-ante portfolio choice, which is only partially addressed in Dasgupta (2004). Furthermore, our focus is on the consequences for systemic risk, and we also study the role of common exposures.

Our results also relate to the literature on information contagion due to common exposures. An early model of information-based individual fragility is Jacklin and Bhattacharya (1988). Chen (1999) shows that bank runs can be triggered by information about bank defaults when banks have a common exposure. Uninformed investors use the publicly available signal about the default of another bank to assess the default probability of their bank. In Acharya and Yorulmazer (2008b), information about the solvency of one bank is a signal about the health of other banks with similar exposure. The funding cost of one bank increases after adverse news about another bank because of correlated loan portfolio returns. Other models of common exposure include Acharya and Yorulmazer (2008a), who analyze the interplay between government bail-out policies and banks' incentives to correlate their investments. Anticipating ex-post information contagion induces banks to correlate their ex-ante investment decisions, endogenously creating common exposures.[5] By contrast, we consider counterparty risk as a principal source of information contagion. We also allow for a larger set of portfolio choice options. While interconnectedness of banks only arises through the endogenous choice of correlated investments in Acharya and Yorulmazer (2008b), we maintain the exogenous correlation of the bank's investment returns as in Acharya and Yorulmazer (2008a) but endogenize liquidity holdings, interbank liquidity insurance, and insurance taken out by early investors against idiosyncratic liquidity shocks.

Leitner (2005) studies the beneficial insurance effects of ex-post financial contagion in the absence of explicit ex-ante risk sharing mechanisms due to limited commitment. Agents with high endowments are willing to bail out agents with low endowments, since the threat of contagion outweighs the costs of the bail-out. While the reaction to ex-post contagion is an ex-post bailout in Leitner's model, we focus on the ex-ante changes in bank choices due to ex-post information contagion under commitment. While both models consider contagion due to counterparty risk, the timing of agents' internalization of the threat of contagion is different. Agents in our

---

[3] Freixas et al. (2000) consider spatial instead of intertemporal uncertainty about liquidity needs.

[4] Postlewaite and Vives (1987) show the uniqueness of equilibrium with positive probability of bank runs in a Diamond and Dybvig (1983) setup with demand deposit contracts. By contrast, we study the impact of information contagion from counterparty risk and common exposures on the ex-ante portfolio choice and systemic risk.

[5] Another consequence of having a common exposure is studied in Wagner (2011), where joint liquidation of an asset induces investors to choose heterogeneous portfolios and forego diversification benefits.

model internalize it ex-ante, while agents in Leitner (2005) react to it ex-post.

Allen et al. (2012) study systemic risk stemming from the interaction of common exposures and funding maturity through an information channel. Banks swap risky investment projects to diversify, generating different types of portfolio overlaps. Investors receive a signal about the solvency of all banks at the final date. Upon the arrival of bad news about aggregate solvency, short-term debt is rolled over less often when assets are clustered, which increases systemic risk. In contrast, we focus counterparty risk as a source of information contagion and its impact on systemic risk.

2. Model

The economy extends over three dates, $t = 0, 1, 2$, and a single good is used for consumption and investment. There are two regions, $k = A, B$, each of which is inhabited by a unit mass of investors and a representative bank. Investors have a unit endowment at the initial date. This paper focuses on systemic risk measured by the probability of the joint failure of banks at the initial date:

$$SR \equiv \mathbf{Pr}(Run_A \wedge Run_B). \tag{1}$$

There are two constant-return-to-scale investment opportunities. First, a safe and liquid asset, such as central bank reserves or government bonds, yields a unit gross return at the subsequent date. Second, regional investment at the initial date, such as loans to the real economy, yields a risky investment return R_k at the final date. We study a bivariate specification of the return:

$$R_k = \begin{cases} R & \text{w.p.}\,\theta_k \\ 0 & \text{w.p.}\,1 - \theta_k \end{cases} \tag{2}$$

where the probability of successful investment (the regional fundamental) is uniformly distributed in each region, $\theta_k \sim U[0, 1]$, and the expected return on investment exceeds the return on the liquid asset, $R > 2$. Liquidation of investment at the interim date is costly and yields a return of $\beta \in (0, 1)$.

2.1. Common exposure

Let $\xi \equiv corr(\theta_A, \theta_B)$ denote the correlation between the regional fundamentals. We contrast two cases: common exposure ($\xi = 1$) and independent fundamentals ($\xi = 0$).

Investors privately learn their preferences at the interim date (Diamond and Dybvig, 1983). Early (late) investors wish to consume only at the interim (final) date. The ex-ante probability of being an early investor, $\lambda_k \in (0, 1)$, is identical across regional investors and equals the proportion of early investors in region k by a law of large numbers. Therefore, the utility of an investor is

$$U_{ik}(c_1, c_2) = \omega_{ik}\, u(c_1) + (1 - \omega_{ik})\, u(c_2), \tag{3}$$

where $\omega_{ik} \in \{0, 1\}$ is the idiosyncratic preference shock with $\Pr\{\omega_{ik} = 1\} = \lambda_k$ and c_t is consumption at date t. The period utility function $u(c)$ is twice continuously differentiable, strictly increasing, strictly concave, and satisfies the conditions $\lim\limits_{c \to 0} u'(c) = \infty$ and $\lim\limits_{c \to \infty} u'(c) = 0$ (Inada, 1963).

Banks provide liquidity insurance to investors by offering a demand-deposit contract. Because of free entry, the bank maximizes the expected utility of its investors (Allen and Gale, 2007). Therefore, investors deposit their endowment with the bank at the initial date. The contract specifies an amount d^k upon withdrawal at the interim date, and an equal share of assets upon withdrawal

at the final date. We focus on essential bank runs as in Allen and Gale (1998, 2007).[6]

2.2. Counterparty risk

The second potential link across regions is counterparty risk, which we introduce via an interbank insurance motive due to negatively correlated regional liquidity shocks as in Allen and Gale (2000). So far, we have focused on the case where the regional returns are correlated, but abstracted from any form of direct link between the two banks. In this section, we focus on the case of uncorrelated regional returns ($\xi = 0$), but introduce negatively correlated regional liquidity shocks as in Allen and Gale (2000). With equal probability, a region has either few withdrawals, $\lambda_L \equiv \lambda - \eta$, or many withdrawals, $\lambda_H \equiv \lambda + \eta$, where $\lambda \in (0, 1)$ is the average withdrawal size and $\eta \in (0, \min\{\lambda, 1 - \lambda\})$ is the size of the regional liquidity shock:

Probability	Region A	Region B
1/2	λ_H	λ_L
1/2	λ_L	λ_H

To insure against liquidity shocks at the initial date, the bank in region k holds interbank deposits b^k with the bank in the other region. The bank that faces many withdrawals at the interim date liquidates its interbank deposits at par. As a result, this bank becomes the debtor bank, since the creditor bank now has a claim on it at the final date. Interbank deposits yield a gross interest rate $\phi \geq 1$ and are senior at the final date (Dasgupta, 2004). The creditor bank can only withdraw at the final date if the debtor bank is solvent. Since the debtor bank may fail due to low investment returns (a solvency shock), interbank linkages expose the creditor bank to counterparty risk.

At the initial date, banks simultaneously choose their portfolios and demand-deposit design. Specifically, banks choose the demand-deposit contract payment d^k, liquid asset holding y^k, interbank deposits b^k, and invest the remainder, $1 - y^k + b^{-k} - b^k$, where $-k$ is the region other than k. We abstract from direct investment in the other region, motivated by limits to monitoring or loan collection skills. Bank choices are publicly observed at the interim date. There is strategic interaction between banks in their choices at the initial date. We study a pure-strategy Nash equilibrium, in which each bank's choice is a best response to the other bank's choice (Nash, 1951).

2.3. Information spillovers

We now turn to the information structure of the model. All prior distributions are common knowledge. Before making their withdrawal decision at the interim date, investors may receive information about the solvency of banks. With probability $q \in (0, 1)$, investors in region k learn the success probability of regional investment, θ^k. Regarding the information about the other regions, we contrast two cases. First, no information is available about the

---

[6] The assumption of essential bank runs implies that a run occurs only when the fundamentals are so bad that liquidation is efficient. Another approach is the global games framework with incomplete information, pioneered by Carlsson and van Damme (1993) and developed by Morris and Shin (2003). Applications to bank runs include Rochet and Vives (2004); Goldstein and Pauzner (2005); Vives (2014); Ahnert (2016); Ahnert and Kakhbod (2017). This approach focuses on coordination among investors who play a non-cooperative game and base their withdrawal or rollover decision on a private signal they obtain about the quality of the bank's asset. In order to focus on ex-post information contagion and its effect on ex-ante portfolio choices, we abstract from such a global games approach. Our simpler approach sets a lower bound on systemic risk, since coordination failure would add to fragility and therefore would exacerbate the benefits of prudential ex-ante portfolio choices that we highlight in this paper.

other region. Second, with probability q, investors learn the success probability of investment in the other region, θ^{-k}.[7] The second case allows us to study the effect of information spillovers at the interim date on the optimal portfolio choice and demand deposit design at the initial date and on the induced level of systemic risk.

Information spillovers occur if investors in one bank learn about the solvency of the other bank. Such information is valuable to investors because of either common exposures or interbank linkages. For common exposures, investment returns are correlated, and knowledge about one bank's solvency helps investors predict the solvency of the other bank (in the absence of information about their own bank's solvency). For counterparty risk, learning about the debtor bank's solvency helps investors predict the solvency of the creditor bank. In sum, information contagion occurs if a run on a bank occurs after its investors learn about the failure of the other bank, provided no run had occurred without the news about the other bank.

Table 1 shows the timeline of events.

3. Equilibrium

In this section, we compute the solvency thresholds below which investors withdraw, the expected utility of investors, and the induced level of systemic risk. We consider the cases of counterparty risk and common exposures both without and with information spillovers. Finally, we discuss several limiting parameter values that admit simple analytical solutions, provide intuition for our model, and benchmark our numerical approach.

We numerically solve for the optimal portfolio choice and the optimal demand-deposit design of banks at the initial date. The model admits a tractable analytical solution only for limiting parameter cases for two reasons. First, corner solutions (e.g., no interbank insurance or no investment) are optimal for some parameter values, invalidating interior solutions and calling for a global approach. Second, some solvency thresholds are non-monotonic in some choice variables. For example, more liquidity is valued when the investment project fails, while less liquidity is valued when the investment project succeeds. In order to solve our model numerically, we assume constant-relative-risk-aversion (CRRA) utility, $u(c) = \frac{c^{1-\gamma}-1}{1-\gamma}$ with $\gamma > 0$. Note, however, that our numerical approach is not limited to this particular choice of functional form for the utility function. We numerically solve for the Nash equilibrium between banks at the initial date. We determine the best response function of a given bank by obtaining the global optimum of the expected utility of investors. Given the choice of the other bank, each bank chooses the triple (b^k, d^k, y^k). Using a discretization on a three-dimensional grid, the expected utility is evaluated at each grid point and the grid point that globally maximizes the expected utility is picked. In a next step, the intersection of best response functions determines the symmetric equilibrium allocations.

3.1. Common exposure

We first consider the case of common exposures ($\xi = 1$) and no counterparty risk ($\eta = 0$). The resulting payoffs of investors are the same functions of bank choices in each region. The final-date consumption level simplifies to $c_{2G}^k \equiv \frac{y^k - \lambda d^k + (1-y^k)R}{1-\lambda}$ in the good state (when the investment return is R) and $c_{2B}^k \equiv \frac{y^k - \lambda d^k}{1-\lambda}$ in the bad state (when the investment return is 0). To obtain these payoffs, note that total resources at the final date comprise liquidity and the proceeds from investment minus the promised amount for all early investors (numerator). These resources are shared among late investors of mass $1 - \lambda$ (denominator). If there is a bank run, full liquidation occurs and the interim-date consumption level is $c_1^k = y^k + (1-y^k)\beta$. Since regions are identical, both banks will optimally choose the same portfolio and demand-deposit design. An essential bank run occurs if and only if the expected utility of final-date consumption, $\theta u(c_{2G}) + (1-\theta)u(c_{2B})$, falls short of the utility of the liquidation value of assets, $u(c_1)$. Therefore, the solvency threshold in either region is

$$\bar{\theta} = \frac{u(c_1) - u(c_{2B})}{u(c_{2G}) - u(c_{2B})}. \tag{4}$$

We use the convention that the solvency threshold is set to zero if $\bar{\theta} < 0$, or to one if $\bar{\theta} > 1$, which is without loss of generality.

First, consider the case without information spillover (no signal about the solvency of the bank in the other region is observed). If investors receive no information, then the situation is unchanged compared to the initial date and they therefore only withdraw from the bank if they are an early type. In contrast, if an investor learns bank health θ, an essential run occurs whenever the solvency level is below the threshold, $\theta < \bar{\theta}$. Thus, the expected utility in the case of common exposure (CE) and the associated level of systemic risk are

$$\begin{aligned} EU_{CE} &= q\left[\bar{\theta}u(c_1) + (1-\bar{\theta})\left(\lambda u(c_1) + (1-\lambda)\frac{1}{2}(u(c_{2G}) + u(c_1))\right)\right] \\ &\quad + (1-q)\left[\lambda u(c_1) + (1-\lambda)\frac{1}{2}(u(c_{2G}) + u(c_{2B}))\right] \end{aligned} \tag{5}$$

$$SR_{CE} = q^2 \bar{\theta}, \tag{6}$$

since both banks fail if investors in both regions receive a signal and this signal is below the threshold.

Second, consider the case with information spillovers. The payoffs of investors and the solvency threshold are unchanged. However, the probability of being informed changes to $q + (1-q)q > q$. Naturally, information spillover increases the probability of being informed. Since fundamentals are identical in the case of common exposures, an investor in a given region either observes the solvency of the regional bank or the solvency of the bank in the other region. Either source of information reveals θ perfectly. Therefore, the expected utility in the case of common exposure and information contagion (CE + IC) places more weight on the first term (where

liquidation may take place) and a smaller weight on the second term (no information and thus no liquidation):

$$EU_{CE+IC} \equiv q(2-q)\left[\bar{\theta}u(c_1)+(1-\bar{\theta})\left(\lambda u(d)+(1-\lambda)\frac{1}{2}[u(c_{2G})+u(c_1)]\right)\right]$$
$$+(1-q)^2\left[\lambda u(d)+(1-\lambda)\frac{1}{2}(u(c_{2G})+u(c_{2B}))\right]$$

(7)

$$SR_{CE+IC}=q(2-q)\bar{\theta}.$$ (8)

Lemma 1. *For a given portfolio choice of banks, information contagion due to common exposure mechanically increases systemic risk:*

$$SR_{CE+IC} > SR_{CE}$$ (9)

Proof. The result arises from equations (6) and (8), noting $q^2 < q(2-q)$ for $0 < q < 1$. □

Our interest is in anticipated information spillovers analyzed in Section 4. That is, we study how the arrival of information about the bank in the other region affects the portfolio choices and demand-deposit design of banks, which may counter the direct effect of greater systemic risk.

3.2. Counterparty risk

Next, we consider the case of no common exposures ($\xi = 0$) but counterparty risk ($\eta > 0$). We describe the consumption levels of investors. We start with the debtor bank (D), which received the liquidity shock at the interim date and withdraws its interbank deposits b^D. Its payoffs are independent of the creditor bank (C). If there is a run on the debtor bank, full liquidation and interbank default occurs, so the interim-date consumption level is $c_1^D \equiv y^D + (1+b^C-b^D-y^D)\beta + b^D$ to all investors. If there is no run, early investors receive d^D at the interim date and the creditor bank withdraws its interbank deposits worth ϕb^C at the final date, so late investors receive $c_{2G}^D \equiv \frac{y^D+b^D-\lambda_H d^D+(1+b^C-b^D-y^D)R-\phi b^C}{1-\lambda_H}$ in the good state and $c_{2B}^D \equiv \frac{y^D+b^D-\lambda_H d^D-\phi b^C}{1-\lambda_H}$ in the bad state.

We now turn to the consumption of investors at the creditor bank (C). The debtor bank withdraws its interbank deposits b^D at the interim date. If there is a run on the creditor bank, all assets are liquidated, including the interbank claim on the debtor bank. The value of this claim is uncertain, yielding $\beta \phi b^C$ if the debtor bank survives (S) and 0 if it fails (F). Thus, the interim-date consumption levels to all investors are $c_{1S}^C \equiv y^C + (1+b^D-b^C-y^C)\beta - b^D + \beta \phi b^C$ and $c_{1F}^C \equiv y^C + (1+b^D-b^C-y^C)\beta - b^D$. If there is no run, early investors receive d^C at the interim date and late investors receive $c_{2GS}^C \equiv \frac{y^C-\lambda_L d^C-b^D+(1+b^C-b^D-y^C)R+\phi b^C}{1-\lambda_L}$ and $c_{2GF}^C \equiv \frac{y^C-\lambda_L d^C-b^D+(1+b^C-b^D-y^C)R}{1-\lambda_L}$ in the good state as well as $c_{2BS}^C \equiv \frac{y^C-\lambda_L d^C-b^D+\phi b^C}{1-\lambda_L}$ and $c_{2BF}^C \equiv \frac{y^C-\lambda_L d^C-b^D}{1-\lambda_L}$ in the bad state.

Consider the debtor bank. Since the behavior of the creditor bank does not affect the payoffs of investors at the debtor bank, information about the creditor bank does not affect the run behavior of investors at the debtor bank. That is, in the case of the debtor bank, information spillover does not matter.

3.2.1. Debtor bank

If investors receive information about the solvency of the debtor bank, an essential bank run occurs if and only if the expected utility of final-date consumption, $\theta^D u(c_{2G}^D)+(1-\theta^D)u(c_{2B}^D)$, falls short of the utility of the liquidation value of assets, $u(c_1^D)$. Therefore, the solvency threshold at the debtor bank is:

$$\bar{\theta}^D \equiv \frac{u(c_1^D)-u(c_{2B}^D)}{u(c_{2G}^D)-u(c_{2B}^D)}.$$ (10)

The probability of failure of the debtor bank is $\bar{\theta}^D$, conditional on investors being informed about solvency, which occurs with probability q.

With probability $1-q$, investors are uninformed about the solvency of the debtor bank and base their essential withdrawal behavior on the prior distributions. Taken together, the ex-ante probability of failure of the debtor bank is $q\bar{\theta}^D$.

We characterize the expected utility of investors at the debtor bank obtained by integrating the payoffs of investors over the realizations of signals, provided that their bank becomes the debtor bank. With probability $1-q$, no signal is received about the solvency of the debtor bank, so early investors, of mass λ_H, receive the promised payment d^D and late investors, of mass $1-\lambda_H$, receive high and low consumption levels with equal probability.[8] With probability q, a signal is received. If the signal is below the threshold $\bar{\theta}^D$, a run occurs and all investors receive c_1^D. If the signal is above the threshold, early investors receive d^D and late investors receive a weighted average of the high consumption level c_{2G}^D and the low consumption level c_{2B}^D, where the weights depend on the solvency threshold. Taken together, the expected utility of investors in the debtor region is:

$$EU^D = (1-q)\{\lambda_H u(d^D)+(1-\lambda_H)\int_0^1 [\theta u(c_{2G}^D)+(1-\theta)u(c_{2B}^D)]d\theta\}$$
$$+q\{\int_0^{\bar{\theta}^D} u(c_1^D)d\theta + \int_{\bar{\theta}^D}^1 \lambda_H u(d^D)+(1-\lambda_H)$$
$$\times[\theta u(c_{2G}^D)+(1-\theta)u(c_{2B}^D)]d\theta\}$$

(11)

Consider the creditor bank. As before, no run occurs if investors in the creditor bank do not receive any information about its solvency. In this case, it also matters whether investors receive information about the solvency of the *debtor* bank. We study the case without and with information spillover in turn.

3.2.2. Creditor bank – no information spillover

The creditor bank is affected by a default of the debtor bank via both the repayment at the final date and the liquidation value of the interbank claim at the interim date. If creditor bank investors are informed about its solvency, but not informed (NI) about the solvency of the debtor bank, the solvency threshold is:

$$\bar{\theta}_{NI}^C \equiv \frac{q\bar{\theta}^D[u(c_{1F}^C)-u(c_{2BF}^C)]+(1-q\bar{\theta}^D)[u(c_{1S}^C)-u(c_{2BS}^C)]}{q\bar{\theta}^D[u(c_{2GF}^C)-u(c_{2BF}^C)]+(1-q\bar{\theta}^D)[u(c_{2GS}^C)-u(c_{2BS}^C)]}$$
$$= \bar{\theta}_{NI}^C(\bar{\theta}^D).$$ (12)

The ex-ante probability of the default of the creditor bank is $q\bar{\theta}_{NI}^C$.

Counterparty risk is reflected by the dependence of the creditor bank's solvency threshold on the debtor bank's solvency. A higher solvency threshold of the debtor bank makes a default on the interbank claim more likely, thus raising the probability of default of the creditor bank, $\frac{\partial \bar{\theta}_{NI}^C}{\partial \bar{\theta}^D} > 0$, since a failure of the debtor bank is a negative externality on investors in the creditor bank.

The behavior of the debtor bank determines whether the creditor bank is repaid. Default of the debtor bank affects both the expected utility from both liquidation and continuation. As the interbank loan is repaid with probability $q\bar{\theta}^D$, the expected utility from liquidation is $q\bar{\theta}^D u(c_{1F}^C)+(1-q\bar{\theta}^D)u(c_{1S}^C)$, where the expectation over the behavior of the debtor bank is taken since its solvency is unobserved (no information spillover). Likewise, the expected utility from continuation is the sum of two terms: (i) with probability $q\bar{\theta}^D$, the debtor bank defaults and late investors of the

---

[8] Without information about the solvency of the debtor bank, and thus no runs, these weights are equal, $\int_0^1 \theta d\theta = \frac{1}{2} = \int_0^1 (1-\theta)d\theta$. This symmetry vanishes once investors receive information about bank solvency.

creditor bank receive $\theta u(c_{2GF}^C) + (1-\theta)u(c_{2BF}^C)$; (ii) with probability $(1 - q\bar{\theta}^D)$, debtor the bank survives and late investors of the creditor bank receive $\theta u(c_{2GS}^C) + (1-\theta)u(c_{2BS}^C)$. Using the solvency threshold given in Eq. (12), the expected utility of investors in the creditor bank is:

$$
\begin{aligned}
EU_{NI}^C &= (1-q)\{\lambda_L u(d^C) + (1-\lambda_L)\int_0^1 [\theta(q\bar{\theta}^D u(c_{2GF}^C) + (1-q\bar{\theta}^D)u(c_{2GS}^C)) \\
&\quad + (1-\theta)(q\bar{\theta}^D u(c_{2BF}^C) + (1-q\bar{\theta}^D)u(c_{2BS}^C))] \, d\theta\} \\
&\quad + q\{\int_0^{\bar{\theta}_{NI}^C} (q\bar{\theta}^D u(c_{1F}^C) + (1-q\bar{\theta}^D)u(c_{1S}^C))d\theta \\
&\quad + \int_{\bar{\theta}_{NI}^C}^1 \lambda_L u(d^C) + (1-\lambda_L)[\theta(q\bar{\theta}^D u(c_{2GF}^C) + (1-q\bar{\theta}^D)u(c_{2GS}^C)) \\
&\quad + (1-\theta)(q\bar{\theta}^D u(c_{2BF}^C) + (1-q\bar{\theta}^D)u(c_{2BS}^C))]d\theta\}
\end{aligned}
\tag{13}
$$

The expected utility and the level of systemic risk in the case of counterparty risk without information spillovers, which is denoted by CR, are

$$
SR_{CR} \equiv q^2\bar{\theta}^D\bar{\theta}_{NI}^C
\tag{14}
$$

$$
EU_{CR} \equiv \frac{EU^D + EU_{NI}^C}{2},
\tag{15}
$$

where the average is taken since the bank has an identical probability of becoming the debtor or creditor bank.

3.2.3. Creditor bank – with information spillover

Allowing for information spillover, investors of the creditor bank receive news about the solvency of the debtor bank and therefore infer whether repayment at the final date occurs and whether the liquidation of the interbank claim yields revenue at the interim date. The creditor bank is not repaid if and only if the solvency of the debtor bank is low, which is a consequence of the seniority of interbank claims. As a result, there are two solvency thresholds of the creditor bank when investors are informed (I): one if the debtor bank fails ($\bar{\theta}_{IF}^C$) and one if the debtor bank survives ($\bar{\theta}_{IS}^C$). Since the solvency of the debtor bank is observed with probability q, these solvency threshold are special cases of Eq. (12) for $\bar{\theta}^D \in \{0, 1\}$, respectively:

$$
\bar{\theta}_{IS}^C \equiv \frac{u(c_{1S}^C) - u(c_{2BS}^C)}{u(c_{2GS}^C) - u(c_{2BS}^C)}
\tag{16}
$$

$$
\bar{\theta}_{IF}^C \equiv \frac{q[u(c_{1F}^C) - u(c_{2BF}^C)] + (1-q)[u(c_{1S}^C) - u(c_{2BS}^C)]}{q[u(c_{2GF}^C) - u(c_{2BF}^C)] + (1-q)[u(c_{2GS}^C) - u(c_{2BS}^C)]}
\tag{17}
$$

For a given portfolio choice at the initial date, these solvency thresholds can be ranked:

$$
\bar{\theta}_{IS}^C < \bar{\theta}_{NI}^C < \bar{\theta}_{IF}^C,
\tag{18}
$$

which captures both positive and negative information spillovers in the context of counterparty risk (solvency of the debtor bank). Similar to Dasgupta (2004), there is a region of fundamentals $[\bar{\theta}_{IS}^C, \bar{\theta}_{IF}^C]$ for which the creditor bank defaults if and only if the debtor bank defaults.

Integrating out, the expected utility of an investor of the creditor bank in the case of information spillovers is:

$$
\begin{aligned}
EU_I^C &= (1-q)\left\{\lambda_L u(d^D) + (1-\lambda_L)\frac{1}{2}[(1-q\bar{\theta}^D)(u(c_{2GS}^C) + u(c_{2BS}^C)) \right. \\
&\quad \left. + q\bar{\theta}^D(u(c_{2GF}^C) + u(c_{2BF}^C))]\right\} \\
&\quad + q\left\{(\bar{\theta}_{IS}^C(1-q\bar{\theta}^D)u(c_{1S}^C) + \bar{\theta}_{IF}^C q\bar{\theta}^D u(c_{1F}^C)) \right. \\
&\quad + \lambda_L(q\bar{\theta}^D(1-\bar{\theta}_{IF}^C) + (1-q\bar{\theta}^D)(1-\bar{\theta}_{IS}^C))u(d^D) \\
&\quad + (1-\lambda_L)\frac{1}{2}((1-q\bar{\theta}^D)[(1-(\bar{\theta}_{IS}^C)^2)u(c_{2GS}^C) + (1-\bar{\theta}_{IS}^C)^2 u(c_{2BS}^C)] \\
&\quad \left. + q\bar{\theta}^D[(1-(\bar{\theta}_{IF}^C)^2)u(c_{2GF}^C) + (1-\bar{\theta}_{IF}^C)^2 u(c_{2BF}^C)])\right\}
\end{aligned}
\tag{19}
$$

where the solvency thresholds of the creditor bank depend on whether the debtor bank fails. That is, the "uninformed" solvency threshold $\bar{\theta}_{NI}^C$ is replaced with the "informed" thresholds $\bar{\theta}_{IS}^C$ and $\bar{\theta}_{IF}^C$.

The expected utility and the level of systemic risk in the case of counterparty risk with information spillovers, denoted by CR + IC, are:

$$
EU_{CR+IC} \equiv \frac{EU^D + EU_I^C}{2}
\tag{20}
$$

$$
SR_{CR+IC} = q^2\bar{\theta}^D\bar{\theta}_{IF}^C.
\tag{21}
$$

Recall that a systemic crisis occurs only if both regions receive an informative signal, which happens with probability q^2. The information spillover from H to L induces a failure of the creditor bank for a larger range of fundamentals ($\bar{\theta}_{IF}^C > \bar{\theta}_{NI}^C$). Again, there are no runs in the absence of information about the bank's own region.

Lemma 2. *For a given portfolio choice of banks, information contagion due to counterparty risk mechanically increases systemic risk:*

$$
SR_{CR+IC} > SR_{CR}
\tag{22}
$$

Proof. The result arises from Eqs. (14) and (21), noting the ranking of thresholds in (18). □

This result arises directly from the fact that a failure of the creditor bank becomes more likely following adverse news about the solvency of the debtor bank, provided the ex-ante choices of banks are unchanged. Therefore, information contagion strengthens the effect of counterparty risk, which leads to a lower level of expected utility and higher systemic risk. In the next section, we analyze how this information contagion channel affects the ex-ante portfolio choices and demand-deposit design of banks at the initial date, which may counter this direct effect of greater systemic risk.

3.3. Limiting parameter cases

Our model admits an analytical solution for several limiting parameter values detailed in this section. These cases help us build intuition for the model. They also verify the validity of our numerical method, confirming the accuracy of our numerical solution for a sufficiently fine grid.

We use the following baseline calibration unless stated otherwise. The period utility function is CRRA, where $\rho > 0$ parameterizes the coefficient of relative risk aversion. Baseline parameter values are $\beta = 0.7$, $R = 5.0$, $\phi = 1.0$, $\lambda = 0.5$, $\eta = 0.25$, $\rho = 1.0$, and $q = 0.7$. Alternative specifications are considered in Appendix B and in Section 4.3 where the variation of each parameter within its feasible bounds is discussed. Our results hold across these various specifications.

First, let the investment return in the high liquidity demand region be below unity ($R \leq 1$). Then, storage dominates investment ($y^* = 1$), which is confirmed by the numerical solution $y_{num}^* = 0.98$. Second, let investors be risk-neutral ($\rho \to 0$), so investment dominates storage since it has a higher expected return. At the same time,

investors do not mind the volatility in consumption induced by idiosyncratic liquidity shocks. Taken together, $d_1^* = 0 = y^*$, which is confirmed numerically ($d_{1,num}^* = 0 = y_{num}^*$). Likewise, if investors are very risk-averse ($\rho \to \infty$), they are not willing to bear any of the investment risk associated with the project or any liquidity risk. Consequently, no investment takes place ($y^* = 1$) and there is full insurance ($d_1^* = 1$). For the numerically feasible and economically useful implementation of $\rho = 200$, we obtain the affirmative results $y_{num}^* = 0.98$ and $d_{1,num}^* = 0.98$.

Third, no risk-averse investor ($\rho > 0$) seeks liquidity insurance in the absence of regional liquidity shocks ($\eta = 0$) for any value of repayment ($\phi \geq 0$). From an ex-ante perspective, liquidity insurance in this case is a mean-preserving spread to both interim-date and final-date payoffs and is rejected by any risk-averse investor. We confirm this intuition numerically ($b_{num}^* = 0$). We also consider the related situation of a positive liquidity shock ($\eta > 0$) but no repayment ($\phi = 0$). Any risk-averse investor would then be partially insured against this risk $b^* > 0$, which is pure ex-ante liquidity insurance. Note that we require $\phi > 0$ in the baseline calibration and all other calibrations to maintain a counterparty risk mechanism. Intuitively, the amount of liquidity insurance decreases in the degree of risk aversion. As investors become more risk-averse, they hold more liquidity as part of the optimal portfolio composition of late investors. The available liquidity serves as self-insurance against regional liquidity shocks at the interim date and is a substitute for interbank insurance. For example, a CRRA coefficient of $\rho = 1$ in our baseline calibration yields $b_{num}^* = 0.15$, while the same calibration with a $\rho = 2$ yields $b_{num}^* = 0.1$.

Fourth, if there are no early investors ($\lambda = 0$), there is no need for insurance against idiosyncratic liquidity shocks. The amount of liquidity held fully reflects the optimal portfolio allocation of late investors ($0 < y^* < 1$) and increases with the level of risk aversion (ρ). These predictions are confirmed numerically in the specification of $\lambda = 0.01$, where the amount of liquidity ranges from $y_{num}^* = 0.42$ in a baseline calibration with $\rho = 1$ to $y_{num}^* = 0.74$ in the baseline calibration with $\rho = 2$. Likewise, if there are only early investors ($\lambda = 1$) it is optimal not to invest in an asset that only matures at the final date and is costly to liquidate ($y^* = 1$). There is no role for liquidity insurance in this specification ($b^* = 0$) as there cannot be any liquidity shocks. Since all resources are used to serve early investors, the optimal interim payment must also be one ($d_1^* = 1$). This intuition is confirmed numerically ($d_{1,num}^* = 0.99$).

Finally, the prior distribution is assumed not to induce liquidation in the case of being uninformed. Hence, no liquidation takes place ($\bar{\theta}_1 = \bar{\theta}_{IS}^C = \cdots = 0$) if investors are never informed in either region ($q_A = q_B = 0$), which is again confirmed numerically.

4. Results

This section summarizes our two main findings. In Section 4.1 we show the existence of an *instability effect* that emerges when information contagion occurs due to common exposures. In Section 4.2 we present a *resilience effect* that arises when information contagion occurs due to counterparty risk. Section 4.3 provides a global parameter analysis, verifying the robustness of our two main results across feasible parameter values.

4.1. Instability effect

We first analyze how information contagion affects systemic risk in a setup with common exposures ($\xi = 1$, $\eta = 0$). Without changes to the ex-ante choice of banks, information contagion results in higher levels of systemic risk (Lemma 1). Essential withdrawals by investors become more likely after adverse news about the solvency of another bank. This situation may correspond to a

bank that receives information about another bank following an unanticipated shock to the other bank. Examples of such shocks may include earthquakes like the Tohoku earthquake in Japan on March 11, 2011, or technical failures such as the computer malfunction at the NYSE on July 8, 2015.

More generally, banks react to ex-post information contagion by adjusting their portfolio choice ex-ante. Specifically, the optimal interim-date payment is unchanged, while the optimal liquidity level is slightly lower (within numerical accuracy) across all baseline cases and feasible parameter choices. However, the changes to the portfolio are small, implying a small indirect effect on systemic risk only. Therefore, the level of systemic risk increases overall once information contagion is present. These results are obtained by comparing the case of pure common exposure (entry (3, 3)) with the case of common exposure and information contagion (entry (4, 4)) in the tables in Appendix B.2. As demonstrated in Section 4.3, this effect is numerically robust.

Result 1. Consider the setup with common exposures ($\xi = 1$, $\eta = 0$). Information contagion has a small effect on the choices of banks at the initial date. As a result, systemic risk increases.

Additional information allows the late investors to decide on early withdrawals in more states of the world and has two consequences. First, liquidation is optimal for late investors following a severe solvency shock. Second, liquidation is detrimental to early investors who only receive their share of the liquidation value and not the (strictly larger) promised interim payment. Therefore, late investors impose a negative externality on early investors. Since the level of liquidity in the case of common exposures is high (to provide self-insurance against investment risk), the second effect is quantitatively small such that additional liquidation increases overall expected utility.

4.2. Resilience effect

We turn to the case of counterparty risk ($\xi = 0$, $\eta > 0$). If the ex-ante choices of banks are unaltered, systemic risk mechanically increases (Lemma 2). This result arises directly from the fact that a failure of the creditor bank becomes more likely after adverse news about the solvency of the debtor bank. Therefore, information contagion strengthens the effect of counterparty risk, which leads to a lower level of expected utility and higher systemic risk. This immediate result is also obtained numerically by comparing entries in the tables in Appendix B.2, notably entry (1, 1) for the case of pure counterparty risk with entry (1, 2) for the case of counterparty risk and information contagion, where both are evaluated at the optimal choices of the pure counterparty risk case (so ex-ante choices are not adjusted).

The focus of this paper is on studying the effect of information contagion on systemic risk, taking information contagion at the interim date into account. As a result, banks alter their portfolio choices at the initial date. Specifically, a bank makes a more prudent portfolio choice to insure risk-averse investors against potential information contagion at the interim date. First, banks reduce the exposure to counterparty risk by engaging in less liquidity co-insurance (lower b). To cover the liquidity demand from early investors, a bank increases the amount of storage (larger y), which is akin to liquidity self-insurance. This reduces the investment in the risky project and funds a larger amount of insurance against idiosyncratic liquidity risk (larger d). The more prudent portfolio choices reduces the range of solvency shocks ($[\bar{\theta}_{IS}^C, \bar{\theta}_{IF}^C]$) for which counterparty risk after information contagion occurs. These results are obtained numerically by comparing the case of pure counterparty risk (entry (1, 1)) with the case of counterparty risk and information contagion (entry (2, 2)) in the tables in Appendix B.2.

The crucial insight is that the mechanical positive effect of information contagion on systemic risk (Result 2) is more than fully compensated for by an indirect negative effect via the change in the ex-ante portfolio choice. Therefore, the overall effect is a *reduction* in systemic risk because of information contagion. We label this the resilience effect. In Section 4.3, we show that this result holds across all feasible parameter values.

Result 2. Consider the setup with counterparty risk ($\xi = 0$, $\eta > 0$). Information contagion induces a more prudent portfolio choice ex ante: liquidity co-insurance, which exposes banks to counterparty risk, is substituted by direct holdings of liquidity (self-insurance) that reduces the investment in the risky project. The overall effect is a reduction in both expected utility and systemic risk.

4.3. Robustness checks

This section shows that the resilience effect and the instability effect are robust to exogenous parameter variations. In particular, we discuss a global variation of parameters by considering the entire range of feasible parameters and study the effect on both systemic risk and expected utility. Details and further analyses, including the optimal portfolio choice and withdrawal thresholds, are contained in Figs. 3–9 in the Online Appendix.

Consider the resilience effect (Result 2) first. Fig. 1 displays the expected utility (dotted line) and systemic risk (dashed line) in the case of counterparty risk and information contagion as a fraction of their respective levels in the case of pure counterparty risk. The resilience effect is present if relative systemic risk is *below* unity. We consider parameter changes of the key variables of the model: the liquidation value (β), the return on investment in the good state (R), the proportion of early investors (λ), and the level of transparency (q). In all cases, the resilience effect prevails.

There are parameters for which the resilience effect is too small and information contagion does not reduce systemic risk. Although the resilience effect does not hold for all parameter values, we can quantify whether or not it holds *on average*. To test this, we formulate the following hypothesis:

Hypothesis 1. Information contagion due to counterparty risk does not reduce systemic risk.

Since we cannot assume that the difference between SR_{CR+IC} and SR_{CR} is normally distributed, we test Hypothesis 1 using the Wilcoxon signed rank sum test. The null hypothesis is that $SR_{CR+IC} = SR_{CR}$. The results of this analysis show a significant difference in systemic risk in the two cases, $z = -116.697$, $p < 0.01$, indicating that systemic risk in the case of counterparty risk and information contagion is significantly lower than in the case of pure counterparty risk.

Turning to the instability effect (Result 1), we see that Fig. 2 displays the expected utility (dotted line) and systemic risk (dashed line) in the case of common exposure and information contagion as a fraction of their respective levels in the case of pure common exposure. Hence, the instability effect is present if the relative systemic risk is *above* unity. We consider the same parameter changes again. In all cases, the instability effect prevails.

5. Conclusion

The aftermath of the failure of Lehman Brothers in September 2008 suggests that information contagion can be a major source of systemic risk, defined as the probability of joint default of banks. One bank's investors will find information about another bank's solvency valuable for two reasons. First, both banks may have invested in the same asset class, such as risky sovereign debt or mortgage-backed securities. Learning about another bank's profitability will help the investor assess the profitability of its bank. Second, one bank may have lent to the other, for instance to share liquidity risk. Knowledge of the debtor bank's profitability helps investors assess the counterparty risk of the creditor bank.

We offer a model of systemic risk with information contagion. News about the health of one bank is valuable for the investors of another bank due to common exposures or counterparty risk. In each case, bad news about one bank adversely spills over to other banks and causes information contagion. We study its effects on the bank's ex-ante choices and the implied level of systemic risk.

We demonstrate that information contagion can *reduce* systemic risk. When banks are subject to counterparty risk, investors in one bank may receive a negative signal about the health of another bank. Given the exposure of the creditor bank to the debtor bank, adverse information about the debtor bank can cause a run on the creditor bank. Such information contagion ex-post induces the bank to hold a more prudent portfolio ex-ante. Banks reduce their exposure to counterparty risk and rely more on self-insurance of liquidity instead of co-insurance. Overall, the level of systemic risk is actually reduced with information contagion. Moreover, the effects of information contagion on systemic risk depend on the source of the revealed information. The case of common exposures, ex-post information contagion increases systemic risk – similar to Acharya and Yorulmazer (2008a).

Appendix A. Figures

Fig. 1. Robustness check. The resilience effect (Result 2) obtains for all parameter variations. We consider variations of β (top left), R (top right), λ (bottom left), and q (bottom right). The figures display expected utility (dotted line) and the level of systemic risk (dashed line) in the case of counterparty risk and information contagion as a fraction of their respective levels in the case of pure counterparty risk.
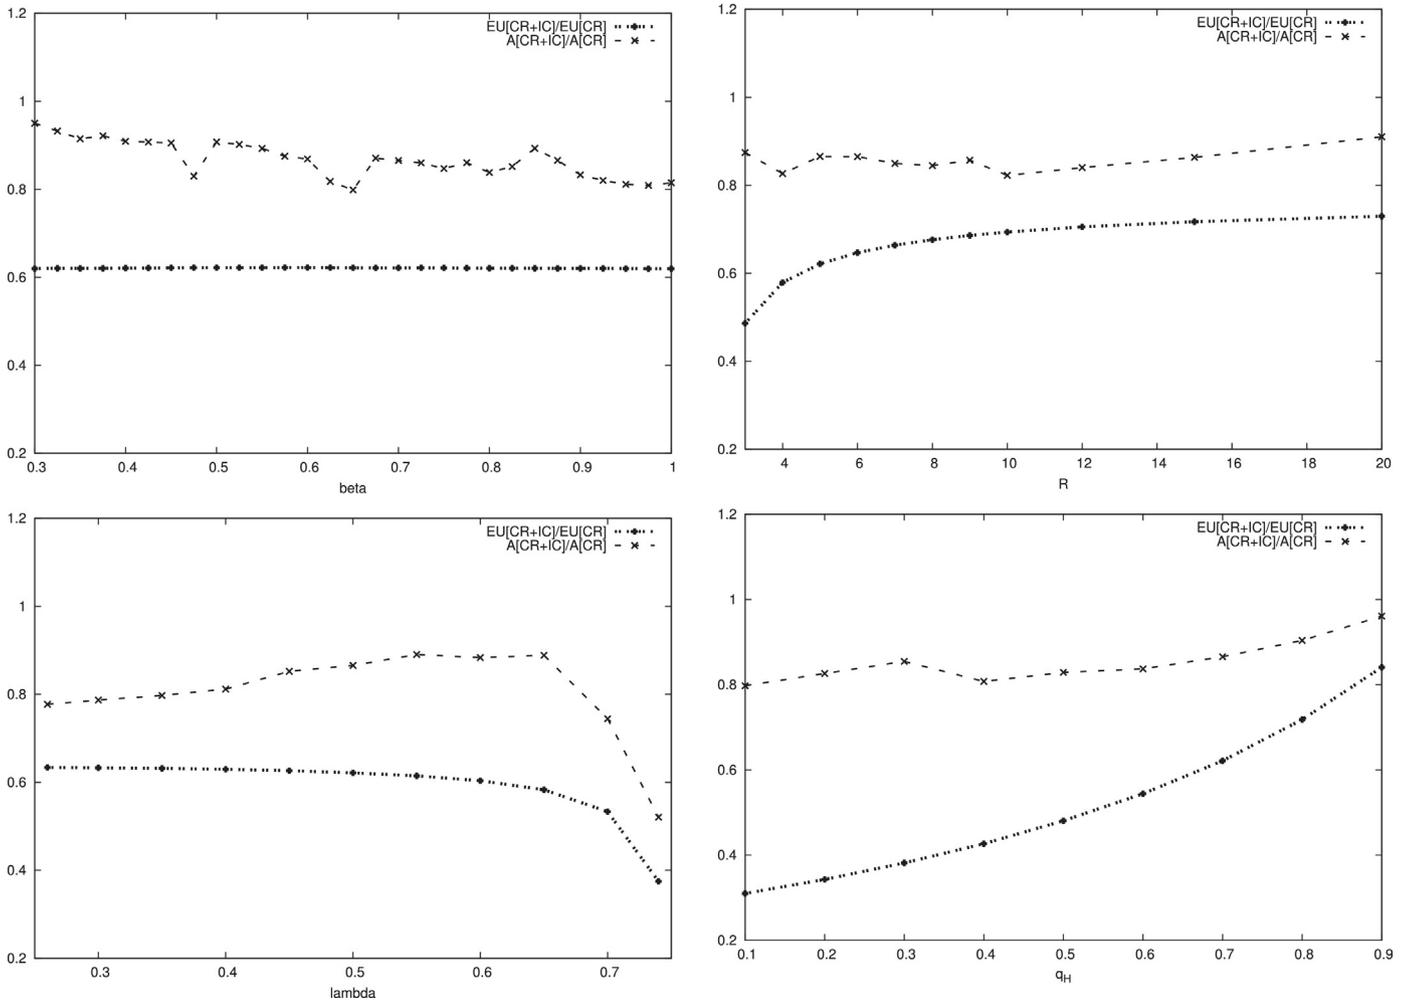

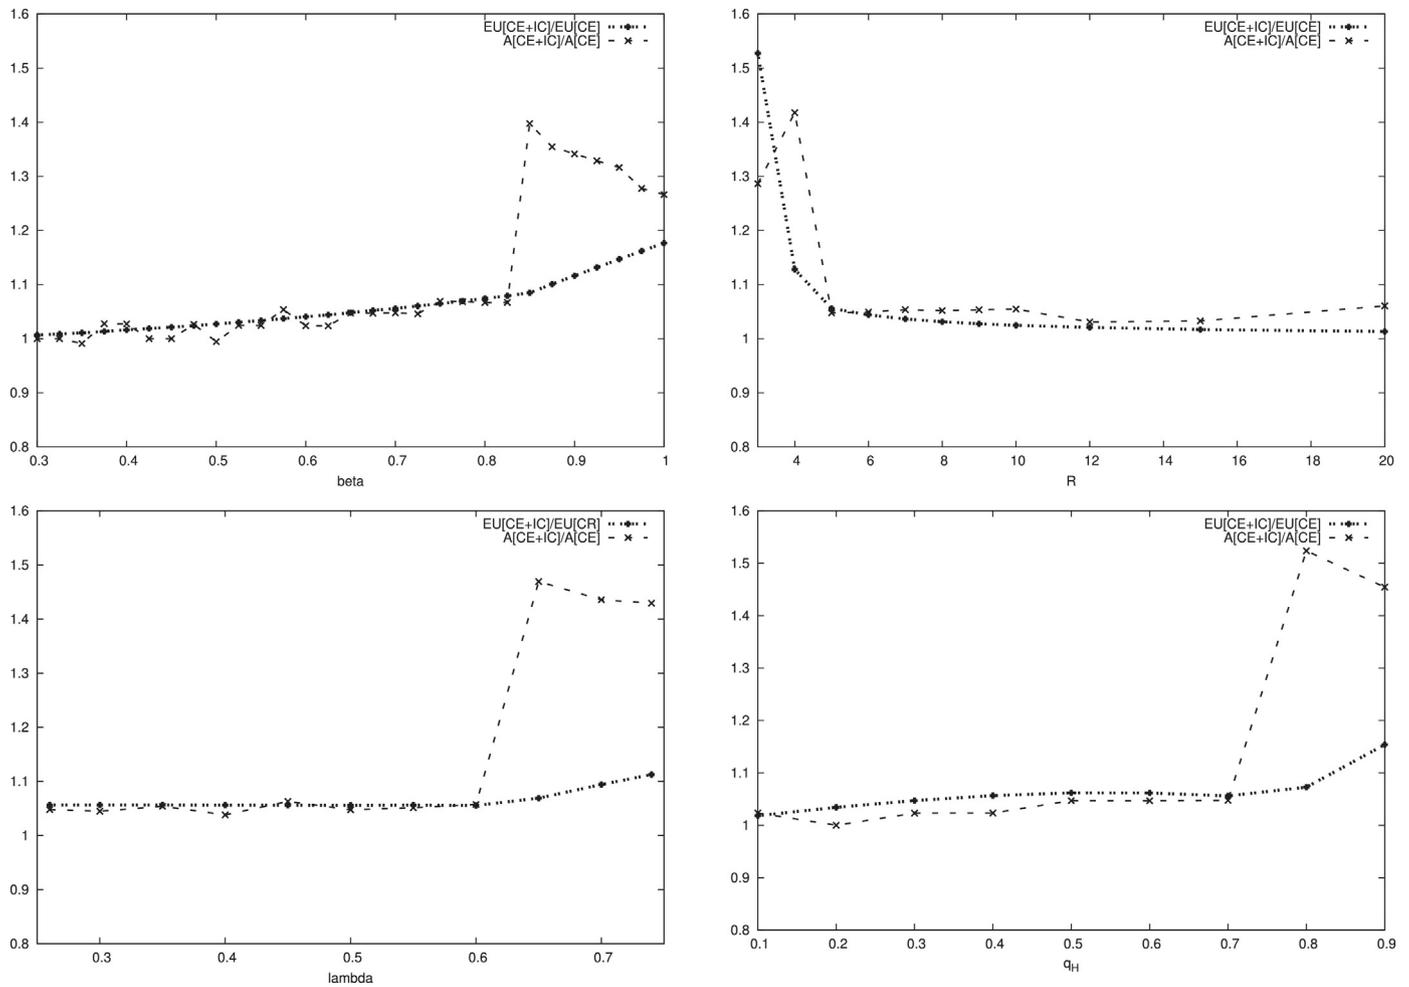

Fig. 2. Robustness check. The instability effect (Result 1) obtains for all parameter variations. We consider variations of β (top left), R (top right), λ (bottom left), and q (bottom right). The figures display expected utility (dotted line) and the level of systemic risk (dashed line) in the case of common exposures and information contagion as a fraction of their respective levels in the case of pure common exposures.

Appendix B. Tables

Section B.1 contains the extreme parameter value benchmarks discussed in Section 3.3 of the main text for additional baseline cases to show the robustness of our numerical implementation. Section B.2 contains the results of Sections 4.1 and 4.2 of the main text. Finally, Section B.3 contains the summary statistics for the parameters used in our global parameter analysis in Section 4.3.

B.1 Extreme parameter value benchmarks

Table 2
Extreme parameter values for four baseline cases. Baseline 1: $\beta = 0.7$, $R = 5.0$, $\phi = 1.0$, $\lambda = 0.5$, $\eta = 0.25$, $\rho = 1.0$, $q = 0.7$. Baseline 2: $\beta = 0.7$, $R = 5.0$, $\phi = 1.0$, $\lambda = 0.5$, $\eta = 0.25$, $\rho = 0.9$, $q = 0.7$. Baseline 3: $\beta = 0.7$, $R = 5.0$, $\phi = 1.0$, $\lambda = 0.5$, $\eta = 0.25$, $\rho = 1.1$, $q = 0.7$. Baseline 4: $\beta = 0.3$, $R = 5.0$, $\phi = 1.0$, $\lambda = 0.5$, $\eta = 0.25$, $\rho = 1.1$, $q = 0.7$.

	Baseline 1	Baseline 2	Baseline 3	Baseline 4

B.3 Global parameter analysis

This section presents details for the $N = 640{,}000$ simulation runs we conducted in Section 4.3 to test whether the resilience effect will hold in the entire parameter space, at least on average.

Table 8

Summary statistics for model parameters.

Variable	N	Mean	SD	Min	p25	Median	p75	Max
R	640,000	5.499	2.599	1.000	3.248	5.498	7.748	10.000
β	640,000	0.500	0.283	0.010	0.255	0.500	0.745	0.990
λ	640,000	0.500	0.144	0.250	0.375	0.499	0.625	0.750
η	640,000	0.125	0.066	0.010	0.067	0.125	0.182	0.240
ϕ	640,000	1.000	0.115	0.800	0.900	1.000	1.100	1.200
q	640,000	0.500	0.289	0.000	0.250	0.499	0.751	1.000
ρ	640,000	1.750	0.433	1.000	1.374	1.749	2.125	2.500

Note: Each parameter is drawn independently of the others from a uniform distribution. R is the positive realization of the return of the risky asset, β the liquidation value, λ the probability of being an early investor, η the size of the liquidity shock, ϕ the price of co-insurance, q the investors' probability of being informed about the solvency shock in the other region, and ρ the risk-aversion parameter for the constant relative risk aversion utility used. SD, p25, and p75 are the standard deviation and the 25th and 75th percentiles of the observable distribution, respectively.

Table 9

Summary statistics for observables in the case with counterparty risk.

Variable	N	Mean	SD	Min	p25	Median	p75	Max
Expected Utility [cr]	640,000	−8.361	495.169	−329,720.656	−2.579	−1.267	−0.834	−0.528
Systemic Risk [cr]	640,000	0.043	0.058	0.000	0.000	0.017	0.060	0.250
Payoff to Early Investors [cr]	640,000	1.042	0.056	0.856	1.010	1.024	1.066	1.486
Self-Insurance [cr]	640,000	0.899	0.064	0.500	0.860	0.910	0.940	0.990
Co-Insurance [cr]	640,000	0.103	0.079	0.000	0.041	0.091	0.151	0.360
Expected Utility [cr + ic]	640,000	-2.2×10^{14}	1.4×10^{15}	-1.0×10^{16}	−2.800	−1.309	−0.848	−0.528
Systemic Risk [cr + ic]	640,000	0.043	0.058	0.000	0.004	0.017	0.053	0.250
Payoff to Early Investors [cr + ic]	640,000	1.027	0.051	0.884	0.996	1.010	1.038	1.486
Self-Insurance [cr + ic]	640,000	0.907	0.061	0.500	0.870	0.910	0.950	0.990
Co-Insurance [cr + ic]	640,000	0.019	0.034	0.000	0.000	0.000	0.032	0.359
Expected Utility [ce]	640,000.000	−8.365	495.169	−329,720.6	−2.582	−1.271	−0.837	−0.543
Systemic Risk [ce]	640,000.000	0.118	0.128	0.000	0.018	0.073	0.171	0.500
Payoff to Early Investors [ce]	640,000.000	1.053	0.080	0.954	1.010	1.024	1.052	1.486
Self-Insurance [ce]	640,000.000	0.902	0.063	0.400	0.870	0.910	0.940	0.990
Expected Utility [ce + ic]	640,000.000	−8.360	495.169	−329,720.6	−2.578	−1.266	−0.833	−0.528
Systemic Risk [ce + ic]	640,000.000	0.247	0.158	0.000	0.120	0.209	0.414	0.500
Payoff to Early Investors [ce + ic]	640,000.000	1.100	0.134	0.940	1.010	1.038	1.136	1.486
Self-Insurance [ce + ic]	640,000.000	0.893	0.072	0.370	0.860	0.900	0.940	0.990
Expected Utility [cr + ic (non-optimal)]	640,000	-2.0×10^{13}	4.5×10^{14}	-1.0×10^{16}	−2.609	−1.281	−0.844	−0.528
Systemic Risk [cr + ic (non-optimal)]	640,000	0.051	0.060	0.000	0.004	0.029	0.075	0.250
Expected Utility [ce + ic (non-optimal)]	640,000.000	−8.365	495.169	−329,720.6	−2.582	−1.271	−0.837	−0.543
Systemic Risk [ce + ic (non-optimal)]	640,000.000	0.226	0.141	0.000	0.119	0.204	0.305	0.500

Note: Expected Utility and *Systemic Risk* (defined as the joint default probability of the two banks) are measured ex-ante. *Payoff to Early Investors*, *Self-Insurance*, and *Co-Insurance* are ex-ante optimal payoffs promised to impatient investors, d_1, the amount of self-insurance y, and the amount of co-insurance b, respectively. [cr] denotes the pure counterparty risk case, [cr + ic] the case of counterparty risk and information contagion, both evaluated at their ex-ante optimal portfolio choices. [cr + ic (non-optimal)] is the case of counterparty risk and information contagion evaluated at the optimal portfolio choice of the pure counterparty risk case. SD, p25, and p75 are the standard deviation and the 25th and 75th percentile of the observable distribution, respectively.
